In the discussion that followed, it was pointed out that a postgraduate course has been designed at the Imperial College of Science and Technology. This represented a co-operative effort between seven disciplines because the interdisciplinary approach was considered to be essential. Another speaker contended that materials science could make its greatest contribution through the development of a common language. We were not disseminating adequately the existing knowledge of materials, and practice in industry tended to lag too much behind research—the growth in knowledge in the field had outstripped the applications. A representative of the Department of Scientific and Industrial Research spoke on the problem of financing materials science teaching and research. Special emphasis was being given by the Department to the needs of materials science, and the long-term financial implications were under investigation. This led to a lively and prolonged discussion on the question of the adequacy of the financial provision, particularly for postgraduate students and courses. Prof. G. Ball (Imperial College of Science and Technology) introduced the subject "the problem of university recruitment" and emphasized what had been said earlier—the tendency of the schoolboy to think in terms of pure science. For this reason alone it might be worth while to retain the word 'science' in the title of courses, with the view of attracting better than average students. In the long term, the social attitude to 'technology' might change. The attitude to materials science as a discipline could be influenced by the provision of suitable text-books for schools. One speaker claimed that pure science was more attractive to the schoolboy by reasons of the so-called 'convertibility' with which it endowed its students, but that it was a mistake, however, to fill higher posts with those trained in narrow specialisms such as rubber or refrigeration technology.

At the third session the chair was taken by Prof. Sproull. Dr. P. E. Evans (Faculty of Technology, University of Manchester), opening a discussion on materials science and the established disciplines, stressed the need for a fresh and unfettered approach to the subject and the importance of engendering thinking in terms of materials from the beginning of the course. A good case could be made out for teaching materials science as a first degree subject. He thought that there might be a danger that the established departments of applied science would regard materials science departments as competitors for limited funds, and, under Britain's present educational system, a limited number of students. The trained materials scientist required is one who not only has specialized knowledge in one field of materials but also has a thorough understanding of materials generally.

Dr. N. F. Astbury (director of Research, British Ceramic Research Association) considered the possible role of a Materials Science Council: whether it could be a viable unit and how it could best operate. He suggested that all rational research is good but only some is timely, and that we are not getting the maximum co-ordination of national effort since much materials research in the United Kingdom is done in a vacuum, thus becoming sterile because it is not stimulated by the materials user. He pointed out that there is no civil agency for co-ordinating materials research in Britain. The relation of a Materials Science Council to existing bodies would be a matter for careful thought, since materials science cuts across several entrenched interests. Opinion would seem to favour a council formed from the relevant existing professional and scientific bodies.

Dr. H. M. Finniston (International Research and Development Co., Ltd.), talking on materials research institutions, suggested that the United Kingdom cannot afford the pursuit of knowledge for its own sake so that 'research' must not always be interpreted as 'pure research'. Any materials research institute would have to be Government supported, interdisciplinary and related to some other continuing function, for example, teaching or industry; it could only be founded at the expense of existing institutions. In general, he was opposed to the foundation of a single national institute. He added that Britain cannot and should not copy the American approach. Mr. Zvegintsov (National Research and Development Corporation), discussing the types of materials scientist needed by industry, said that the paradox in science and technology in this field was the requirement for greater specialization with greater hybridization. He stressed that the essential background knowledge required was the relation of properties to structure and that the need for the imaginative creative step was increasing.

In the discussion that followed, it was suggested that a Materials Science Council could collate and disseminate information on existing and proposed materials science courses in addition to promoting conferences on themes cutting across several disciplines. It was said that Britain cannot afford a proliferation of research institutions.

In conclusion, it was agreed that the following items summarized the tenor of the conference:

(1) There is a real need for an expansion of existing postgraduate courses in materials science.

(2) There should be a limit to the number of institutions offering courses in materials science because such an institution must be of a minimum size before it can be effective.

(3) The best kind of materials science course is organized by cutting across the boundaries of departments of both pure and applied science.

(4) The lack of Department of Scientific and Industrial Research advanced studentships is a grave handicap to the development of materials science courses.

(5) There appears to be no case to support any plan for setting up special research institutions to be devoted to materials science.

(6) Experience in materials science courses so far shows that it will be necessary to interest the schoolmaster and the schoolboy in this subject. There are various ways in which this can be done, but one which calls for attention is the re-writing of parts of school physics text-books.

(7) It has been stated that the reason why schoolmasters recommend that their best students read pure science is because physics and chemistry are more 'convertible' than a subject like materials science or a technological subject. This is questioned. Experience from such universities as Sheffield shows that graduates in technological subjects are at least as adaptable as graduates in pure science.

(8) Sir Harry Melville, secretary of the Department of Scientific and Industrial Research, would welcome the opportunity to meet representatives of the universities and colleges of advanced technology concerned with materials science and technology, to discuss the forward planning of teaching and research.

It was resolved to hold a further conference on the same theme in 1964. Prof. Mitchell, of the University of Reading, has agreed to co-ordinate the arrangements for this.

DELTAIC AND SHALLOW WATER MARINE SEDIMENTATION

THE sixth International Sedimentological Congress, held in the Netherlands and Belgium during May 29–June 2, was attended by about 300 members from more than 20 countries. It was preceded by field trips to study the Dutch Holocene deposits, especially the tidal flat sediments of Zeeland and the coastal plain west of Amsterdam, and the lagoonal deposits of the East Flevoland polder.

The earlier sessions of the Congress were held in Amsterdam, the later ones in Antwerp. The main theme of the Congress was "Deltaic and Shallow Marine Deposits" though some papers of a general nature were also presented. After speeches of welcome by the president of the Organizing Committee, Prof. R. Tavernier, the president of the International Association of Sedimentologists, Prof. F. P. Shepard delivered his presidential address on "Criteria in Modern Sediments Useful in Recognizing Ancient Sedimentary Environments". This appropriately dealt in considerable part with the work of the speaker and his colleagues in and around the Mississippi Delta. Prof. Shepard stressed the importance of the extensive Cænozoic tectonic activity on recent sedimentation and commented on the discovery in deep water of an increasing number of sedimentary features once regarded as indicative of shallow water origin.

Only about one-third of the papers accepted by the Congress for publication could be read and discussed at the meeting. Descriptions of recent or relatively recent deltas dealt with those of the Niger (J. R. L. Allen) and of the Rio Grande de Santiago off west central Mexico (D. G. Moore). R. H. Dott discussed the incidence of deltaic deposition in eugeosynclinal belts, with special reference to the United States, and P. Wurster described the deltaic sedimentation of the German Keuper.

Studies of modern shallow water marine sediments included accounts of transportation and deposition along the Dutch coast (A. J. de Groot) and off Brest (A. Guilcher). H. Füchtbauer discussed the varying porosities of sediments from different environments in the southern North Sea. A paper arousing widespread interest was that in which E. J. Degens described the diagenesis of organic substances off the Californian coast and reached the conclusion that the organic matter was almost entirely land derived. Modern carbonate sedimentation in the Persian Gulf was described in papers by D. J. J. Kinsman and by A. J. Wells. The patches of milky water, known as 'whitings', from which large-scale precipitation of calcium carbonate occurs were illustrated by a short film. Two other excellent films were shown in the course of the meeting, one illustrating the formation of various types of ripples, bars and dunes in flume experiments, the other submarine erosion by slow-moving sediments.

Older shallow-water deposits described included, among others, marginal Tertiary sediments of the Paris basin (C. Pomerol) and of the sub-Alpine molasse trough (W. Zimmerle). J. P. Mangin claimed an extremely shallow-water origin for sequences interpreted as 'flysch' in the Cretaceous and Eocene rocks of northern Spain. R. Goldring discussed the significance of the two distinct trace-fossil assemblages commonly met with in shallow-water marine sediments. A number of contributors dealt with British Carboniferous sedimentation in South Wales (G. Keeling and T. R. Owen) and in central and northern England (H. G. Reading, P. M. L. Duff and E. K. Walton). G. V. Chilingar, in a study of more than 600 core samples, showed that for sandstones of comparable grain size a close relation exists between porosity and permeability.

During the Congress a special one-day symposium on "Sedimentology and Ore Genesis" was held in Delft. The opening session dealt with syngenetic sulphide deposition. A. J. C. Bernard discussed the importance of adsorption and of precipitation at surface temperatures in metallogenesis. O. Schulz claimed the lead-zinc deposits of Raibl and Bleiberg as of exhalative sedimentary origin, while H. J. Schneider regarded these and other deposits in Triassic limestones and dolomites of the Eastern Alps as due to syn-sedimentary precipitation in the back reef facies. P. Nicolini drew on Moroccan examples as well as those of Mansfeld and of deposits in the Cévennes in illustration of his theories of sedimentary concentration of copper, lead and zinc. L. G. Love described, with convincing detail, the early diagenetic formation of pyrite in recent muds. G. C. Amstutz illustrated the development of four generations of diagenetic iron sulphide from Ordovician dolomitic limestones in Missouri. In collaboration with P. Ramdohr, he quoted mineralogical evidence interpreted as indicative of pre-deformation and even pre-slumping deposition of much of the sulphide at Mount Isa.

A second session dealt with sedimentary iron ore deposits. J. Petránek described the evidence for shallow-water origin of the oolitic ores of the Lower Palæozoic. H. Harder drew a comparison between ores of the Minette type to which the iron was supplied by normal weathering processes and those of the Lahn-Dill type in which it is believed to have come from volcanic sources. L. Bubenicek considered the conditions of deposition of the Lorraine ores stressing the importance of diagenesis. A final session dealt with the origin of phosphorites (M.Slansky), of strontiobarytes from the German Zechstein (H. Puchelt and G. Müller) and of the Arkansas barytes deposits (R. A. Zimmermann and G. C. Amstutz). The papers and the ensuing discussion, ably summarized at the close by P. Routhier, are to be published as a separate volume from the remainder of the Congress proceedings.

After the Congress, seven different excursions in Belgium offered opportunities for studying a variety of sedimentary formations. At the general assembly of the International Association of Sedimentologists a proposal to hold the seventh congress in Great Britain in 1967 was unanimously approved.

J. H. Taylor

CONFERENCE OF THE UNIVERSITIES OF THE UNITED KINGDOM

THE report of proceedings of the Conference of the Universities of the United Kingdom*, held in London during December 14–15, 1962, includes the text of the speeches of Dr. E. G. Edwards and Prof. S. Wiseman in opening the discussion on alternatives to university education, and of Sir Noel Hall and Prof. A. G. Quarrel in opening the discussion on relations between the universities and industry, as well as of that of contributions to both discussions.

Dr. Edwards was concerned more especially with the deliberate interaction of college and industry attempted

* Conference of the Universities of the United Kingdom 1962: Report of Proceedings—Alternatives to University Education; Relations Between the Universities and Industry. Pp. 92. (London: Association of Universities of the British Commonwealth, 1963.) 5s.

by the colleges of advanced technology and with its implications for postgraduate study and research, education and industrial training generally, while Prof. Wiseman examined the part played by teacher training colleges as 'alternatives' to a university education. Both speakers insisted on the need to provide for some cross-over or transfer from college of technology or teacher training college to university and vice versa and on the importance of a broadly based education. Dr. P. F. R. (now Sir Percy) Venables referred to the necessity for all institutions of higher education to think in terms of university quality in determining their conditions, and in particular there should be adequate opportunities for higher study and research and professional contacts by way of travel, sabbatical leave and attendance at conferences. Prof. Wiseman's contention that the provision of teaching should be under the ægis of the universities was fully supported, but sandwich courses were not generally accepted as advantageous.

Sir Noel Hall thought that up to 1939 contacts between the university world and industry generally were much more limited in number and scope than those in other advanced countries and quite inadequate for the post-war demand, although in finance and public administration a pattern of relations had developed where practitioners welcomed discussion with university men and women on the problems of their own day-to-day responsibilities. Much re-thinking was now taking place in industry, and probably among university appointments committees, on the placement of graduates in industry, leading to developments which were steadily improving contacts between universities and industry in this respect. He thought that research by qualified university people into the activities of industry itself was likely to continue to be difficult to organize and pursue, though he was not particularly concerned about the problem of secrecy. A greater difficulty was that of deciding the point in time at which important decisions had in fact been taken. This difficulty appeared to be diminishing and much activity was also being devoted to studying the tools of management.

Prof. Quarrell was concerned more with the conduct of research by universities on behalf of industry, discussing more particularly the research contract but emphasizing the value of formal opportunities for personal contacts between industrialists and members of a university through the university court, council and committees of council. In this discussion also the importance of a wider basic training for professional students was emphasized. However, the main stress was laid on the importance of personal contacts, including participation by industrialists in university government at the executive level. The desirability of avoiding the use of the term 'management' was recognized and of referring rather to 'business studies'.

THE BRITISH COAL UTILIZATION RESEARCH ASSOCIATION

THE annual report for 1962 of the British Coal Utilization Research Association* includes a summary of the year's activities and lists of publications and lectures by the staff, information circulars, and membership of advisory committees and of research staff. The total staff of 310 at the end of the year comprised 63 in scientist grades, 115 in research officer and research assistant grades, 46 in clerical and administrative grades and 86 in industrial grades.

The bulk of the report is occupied by an account of research activities from which the following points are selected. A two-year programme on coal-fired boilers fitted with automatically controlled combustion equipment and ash-handling and coal-handling gear indicated that from the point of view of cost of steam generated as well as technically this assembly of coal-fired equipment can be recommended for industrial use in many localities and circumstances. Eight commercially produced solid-fuel boilers with outputs from 33,000 to 60,000 B.Th.U./h have been tested using anthracite and coal under varying conditions to provide basic information for developing more efficient and automatic appliances with high amenity.

* The British Coal Utilization Research Association. Annual Report, 1962. Pp. 67. (Leatherhead: The British Coal Utilization Research Association, 1963.)

Work on deposits and corrosion in large water-tube boilers has already indicated that the composition and structure of deposits are independent of time, and has led to the devising of an infra-red spectrometric method for determining sulphur trioxide and to the investigation of laboratory methods for assessing quantitatively the effects of the nature of the ash and the composition of the flue gases on the corrosion of austenitic steels.

A systematic study of the slagging properties of British coals now nearing completion should assist in the choice of coals for slagging combustion, and basic studies of combustion and gasification have sought to provide basic information on the behaviour and decomposition of coals while being heated. The apparatus for studying pre-ignition and devolatilization of small particles of coal has been further developed, enabling the amount and rate of decomposition at known particle temperatures to be determined under effectively isothermal conditions. Among instrumental advances during the year were the further improvement of the venturi pneumatic pyrometer, the use of a nuclear magnetic resonance method, a microwave method for continuous measurement of moisture in coal, and the use of ciné-photography for studying the operation of the open-screw feeder and the quenching of slag discharged from a gasifier.

TRIBOPHYSICS RESEARCH IN AUSTRALIA

THE Division of Tribophysics of the Commonwealth Scientific and Industrial Research Organization of Australia is a major centre of research on the physics and chemistry of surfaces of solids and on metal physics. The annual report for 1961–62 records that work continued on the friction and lubrication of surfaces*. Molybdenum disulphide has been shown to be superior in lubricating ability to many other inorganic compounds of comparable structure, and the effect of atmospheric humidity and water absorbed on the lubricant on burnishing and friction has been examined. Friction is highest at 100 per cent humidity. The theoretical study of how models of the atomic configurations of flat surfaces could, in principle, be constructed has now been applied to a number of different crystal structures and a set of photographs of models of about twenty of the simplest surfaces in each of the face-centred-cubic, body-centred-cubic, sodium chlor-

* Commonwealth of Australia. Commonwealth Scientific and Industrial Research Organization. Annual Report of the Division of Tribophysics for the year ending June 30, 1962. Pp. i+19. (Melbourne: Division of Tribophysics, C.S.I.R.O., 1962.)

ide, diamond and hexagonal closed-packed structures has been produced. The preparation of surfaces in high vacuum, the examination by electron microscopy of metal films evaporated on to glass, and the effects of bombarding gold with inert gas atoms have been studied. The oxygen adsorption on, and possible solution in, a clean silver surface at about 200° C, in the range 10^{-3}–5×10^{-2} mm of mercury pressure was measured and the quantity related to the surface area of the silver determined by the adsorption of krypton at −195° C. The quantity of oxygen sorbed per unit area and the shape of the isotherm depended markedly on the surface to volume ratio of the evaporated film. The surface appeared to be covered with a monolayer at approximately 5×10^{-3} mm of mercury pressure and the amount of oxygen adsorbed at that pressure corresponded to one oxygen atom for every krypton atom absorbed.

For the preparation of metal specimens for X-ray and electron microscope measurements a spark erosion machine was developed and the amount and depth of the damage produced by the machine on nickel was studied. Other investigations included the effects of surface, temperature and strain rate on the Bauschinger effect and cyclic work-hardening in copper single crystals; the measurement of the electrical resistivity of dislocations; the formation of point defects in plastically deformed metals and the dislocation rearrangements during recovery; and martensite transformations in steel. For the Divisions of Textile Physics and Protein Chemistry proton resonance studies of the kinetics of the absorption of water by wool and the exchange of deuterium for hydrogen in a particular wool–water system were made, and in conjunction with the Division of Applied Mineralogy the properties of interlayer water in vermiculite crystals were investigated.

The annual report includes details of the publications by the members of staff of the Division and a list of the names of the senior members of staff. Dr. L. M. Clareborough, Dr. M. E. Hargreaves and Mr. M. H. Loretto received the David Syme Research Prize for their work on imperfections in metal crystals and Dr. A. K. Head was visiting professor at Brown University, Rhode Island. Prof. P. P. Ewald, president of the International Union of Crystallography, visited the Division in October 1961.

S. Weintroub

CLEAN SURFACES AND SURFACE PHENOMENA IN SEMICONDUCTORS

A RECENT issue of the *Annals of the New York Academy of Sciences* contains the series of papers presented at the conference entitled "Clean Surfaces" held by the Academy during April 5–7, 1962, and, as a supplement, the papers of the symposium on "Surface Phenomena in Semiconductors" held by the American Chemical Society during March 21–29, 1962*.

The conference was divided into four parts, the first of six papers dealing mainly with electron diffraction and the electronic properties of clean surfaces; the second of six papers with cleaved and etched surfaces; the third of three papers with adsorption; and the fourth of six papers with nucleation. E. W. Müller gave a survey of field emission microscopy of clean surfaces with electrons and positive ions. He stressed that the field ion microscope is a research tool for the investigation of clean surfaces, and of the defect structure in the interior of metal crystals exposed at the surface by field evaporation. More detailed information on adsorption can be expected by the operation of the microscope with gases of lower ionization energy, but this will require ultra-pure imaging gases, and the lower field strength will reduce the resolution of the microscope. L. H. Germer discussed the very recent applications of the diffraction of slow electrons to the investigation of surfaces and the new science of two-dimensional crystallography. Experiments described by H. E. Farnsworth of low-energy electron diffraction from a cleaved germanium surface have established that crystal faces other than that desired by cleavage were present, and that a cleaved surface had a larger area of undesired crystal facets than a surface prepared by cutting the crystal with a diamond wheel, ground, etched chemically, and cleaned *in vacuo* by argon ion bombardment and subsequent annealing.

The symposium on "Surface Phenomena in Semiconductors" was suggested and organized by H. van Olphen, the chairman of the division of colloid and surface chemistry of the American Chemical Society. The object was to stimulate discussion among surface chemists and research scientists in the semiconductor surface field. The symposium was tutorial in character and the fourteen papers presented comprise a series of review or tutorial papers each devoted to a particular area of specialization.

* *Annals of the New York Academy of Sciences*, **101**, Article 3: *Conference on Clean Surfaces*, with Supplement: *Surface Phenomena in Semiconductors (Symposium)*. By F. G. Allen *et al.* Pp. 583–1014. (New York: New York Academy of Sciences, 1963).

The introductory review by W. R. Savage (Texas Instruments Inc.) covers the general field of the properties of semiconductor surfaces. J. N. Zemel (United States Naval Ordnance Laboratory) describes several fundamental physical measurements used in semiconductor surface research and their connexion with some of the main streams of contemporary work. He mentions that the properties of surface states on only five materials (germanium, silicon, zinc oxide, lead sulphide and indium antimonide) have been studied to any extent. The investigation of a clean semiconductor surface is a difficult and challenging pursuit, because whereas a metal surface with a hundredth of a monolayer is considered acceptably clean for thermionic work, such a density of contamination on a semiconductor would produce, if diffused in 10^{-4} cm, a degenerate layer of width equal to the surface space charge region. It is not surprising, therefore, that he concludes that though there is a great deal known about the surfaces of semiconductors, there is little understanding. Field emission as a tool, and the grain boundary as a system, for the study of surfaces are discussed by F. G. Allen (Bell Telephone Laboratories Inc.) and P. Handler (University of Illinois) respectively. Lifetime and conductivity measurements on clean germanium surfaces are reviewed by Y. Margoninski (Raytheon Research Division) and the pulsed field effect method of investigation of surface states on semiconductors by G. Rupprecht (Tyco Laboratories Inc.).

Several papers deal with aspects of surface chemistry and electrochemistry. M. Green (University of Pennsylvania), in a paper entitled "The Configuration of Complexes on Semiconductor Surfaces", discusses a new approach to the problem of the equilibrium configuration of surface layers which should be useful in problems of chemisorption, film nucleation and related phenomena. The reaction between heated germanium and oxygen, and between water and methyl alcohol is reported on by M. J. Sparnay (Philips Research Laboratories), and H. C. Gatos and M. C. Lavine (Massachusetts Institute of Technology) discuss the process of formation of thermal etch figures on germanium single crystals when heated to temperatures of 700°–925° C in the presence of argon–oxygen mixtures.

An interesting and instructive paper of the series, though it did not produce any comment in the final panel discussion session of the symposium, was that of N. J.

Harrick (Philips Laboratories) on total internal reflexion and its application to surface studies. The absorption of infra-red radiation in semiconductors has been used successfully to study bulk properties of semiconductors, but through the use of multiple total internal reflexion, the space-charge region can be probed and the properties of the carriers in the space charge region can be measured. Because of the special characteristics peculiar to total internal reflexion, both the outside and the inside of the surface can be studied. After a clear description of the process of internal reflexion and of some of the well-known, but nowadays rather neglected, beautiful optical demonstrations of fundamental phenomena associated with internal reflexion, Harrick discusses the application to surface studies. The experimental arrangement and preparation of the samples are described, and details are given of the results of investigations by various workers on chemisorbed molecules, oxide growth and thin films. Finally, various possible experimental studies, using infra-red radiation to obtain information concerning the space charge region on semiconductors are suggested and outlined.

S. WEINTROUB

ELECTRON-PROBE MICROANALYSIS OF ANODIC OXIDE FILMS ON ALUMINIUM ALLOYS

By DR. G. C. WOOD, V. J. J. MARRON and B. W. LAMBERT

Department of Chemical Engineering, Faculty of Technology, University of Manchester

IN view of the successful application of electron-probe microanalysis to the qualitative and quantitative analysis of oxide scales on alloys[1,2], it appeared desirable to examine the possibilities of the technique when applied to the examination of corrosion products obtained in aqueous media. In particular, the field of the formation, transformation and dissolution of anodic films, and indeed of the reactions between all types of semi-conducting films and electrolytes, is extremely important and likely to receive increasing attention. Anodic oxide films on aluminium alloys were chosen for preliminary studies because they are readily reproducible, their general properties are sufficiently well documented to enable comparisons to be made and metallographic preparation for the microanalyser is simple. In addition, it was felt that further useful information about their formation, dyeing, sealing and corrosion properties could be obtained.

Consequently, six small sheet specimens of an aluminium–magnesium alloy (magnesium 5·00, manganese 0·25, copper 0·01, iron 0·24, silicon 0·01, wt. per cent) were chemically polished and anodized at 25 m.amp/cm² in stirred 15 per cent w/v sulphuric acid at 15° C for 60 min. Individual specimens were then subjected to one of the following treatments: (1) dabbed with filter paper to remove surplus surface acid; (2) washed for 1 min in running distilled water; (3) washed for 24 h by rotation in distilled water; (4) sealed in potassium dichromate solution (50 g/l.) at 95° C for 1 h; (5) sealed in a conventional nickel acetate solution (nickel acetate 6 g/l., boric acid 8 g/l.) at 95° C followed by smudge removal with a clean dry rag; (6) sealed in concentrated nickel acetate solution (nickel acetate 60 g/l., boric acid 80 g/l.) at 95° C with subsequent smudge removal.

A further specimen was prepared under similar anodizing conditions at 30° C and washed for 1 min.

The specimens were then set in small electrically conducting mounts and cross-sections prepared metallographically in a conventional manner, finishing on 1μ diamond suspension. Optical examination showed that films formed at 15° C were 45–48μ thick, indicating very little dissolution at the outer surface during formation, whereas the film produced at 30° C was only 30μ thick because a third of it had been completely dissolved. Static probe measurements of aluminium, magnesium and sulphur concentrations, and of nickel and chromium concentrations where appropriate, were made at short intervals in the films along lines of traverse normal to the metal/oxide interface using a Cambridge 'Microscan' microanalyser. The apparent percentages of the elements were determined by comparison with appropriate standards, the results being corrected for background radiation and dead-time but not generally for absorption because of the complex and uncertain nature of the X-ray source in the specimens. Some of the more important trends are illustrated in Figs. 1–3.

The distributions of aluminium across films formed at 15° C and 30° C respectively, followed by washing for 1 min, are compared in Fig. 1. For the former specimen the aluminium concentration is virtually constant with a slight hint of lower values towards the outer interface, although this trend is masked by the scatter. Clearly there is little extra dissolution in the pores or at the outer surface in this case. The aluminium content of the unwashed specimen (not shown on the diagram) was slightly higher, probably due to Al^{3+} ions in the liquid in the pores, but for the other washed and sealed specimens was very similar. On the other hand, the partly dissolved film formed at 30° C shows a pronounced reduction of apparent aluminium content from 30 wt. per cent near the alloy to 11 wt. per cent near the solution, indicating extra dissolution in the pores. These results support the view that the truncated-cone pore model[3] must be largely due to extra dissolution rather than inherent in the mechanism of film growth. The apparent aluminium contents are somewhat low when compared with the figure of 37 per cent aluminium given for a typical anodic film[4]. This is

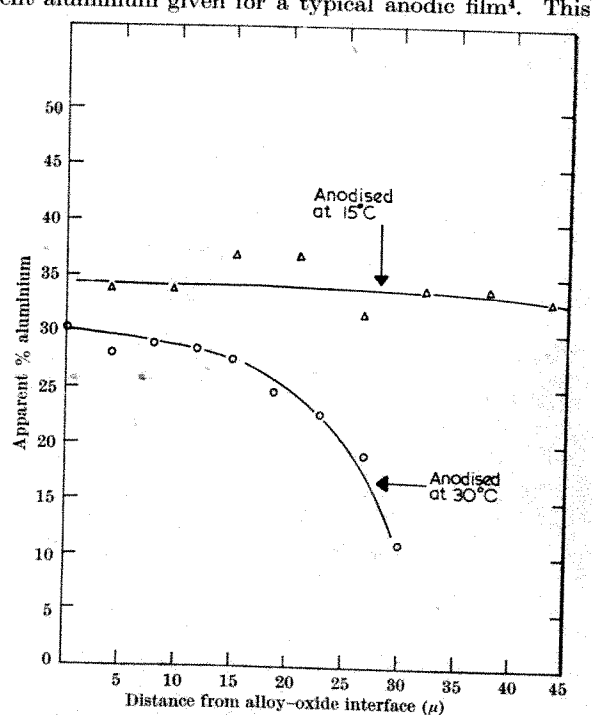

Fig. 1. Influence of anodizing temperature on aluminium distribution.

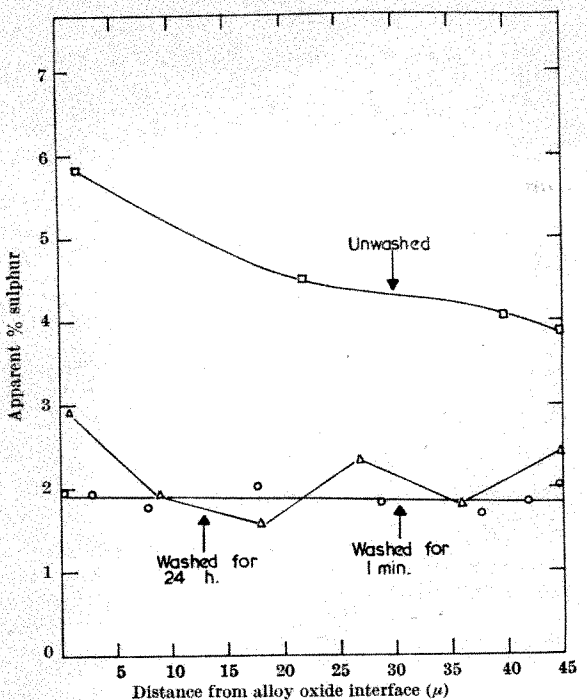

Fig. 2. Influence of post-anodizing treatments on sulphur distribution

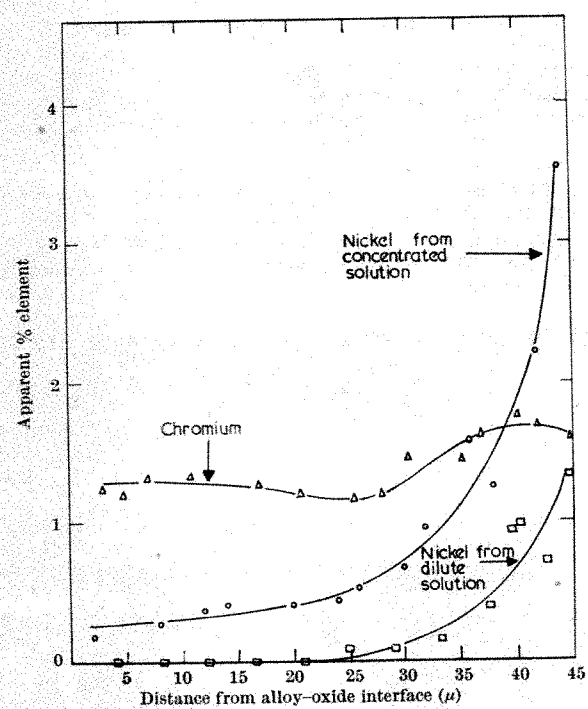

Fig. 3. Distribution of chromium or nickel produced on sealing

partly accounted for by the magnesium in the film, but greater errors are probably incurred due to the uncertain nature of the X-ray source and by absorption effects. A crude estimate of the absorption of aluminium radiation shows that the true figure near the alloy/oxide interface of the 15° C specimen should be nearer 48 per cent aluminium. This figure seems somewhat high and, bearing in mind the uncertainties in the corrections, it appears desirable to quote the measured values only.

Magnesium was detected in the films but with insufficient accuracy to show any trends. The distribution of a heavy alloying element such as copper would be measured easily and accurately.

Fig. 2 illustrates the sulphur distribution in washed and unwashed specimens. The reduction in sulphur content towards the outer interface of the unwashed specimen is almost certainly due to desorption of acid from the pores by the filter paper used for drying or by the mounting material. Washing readily removes more than half the sulphur in the film, and indeed washing for 1 min appears as effective as for 24 h, a point which was made on other evidence elsewhere[5]. The sulphur is readily removed from the pores but not from the bulk of the pore walls. If prolonged washing is really important for some post-treatments, as is sometimes indicated, it must be because of the removal of final traces of acid from microfissures or because of reconditioning of the pore sides. The undulations in sulphur content in the washed specimens are probably not genuine but are due to relief polishing or the difficulty in accurately measuring low concentrations of a light element. The scatter may be very little as for the specimen washed for 1 min, or considerable as for the specimen washed for 24 h. The apparent sulphur contents before and after washing are in good agreement with the literature[6].

The distributions of chromium and nickel obtained on sealing in the appropriate solutions are shown in Fig. 3. There is little variation in the chromium content, the measured values lying between 1·15 and 1·75 per cent. The enrichment near the outer surface is probably genuine due to the slightly greater porosity and readier replenishment of electrolyte in this region, but the slight fall in concentration near the centre of the film is not significant. The chromium concentration is about ten times as great as would be explained by the mere replacement of liquid in the pores by dichromate solution. Clearly, as the metal-containing anions are incorporated into the pore walls, fresh ones enter the pores, as previously demonstrated by Edwards[7]. This view is in harmony with impedance measurements which show that pore closure due to simultaneous hydration is slow in dichromate sealing during the early stages[5].

No nickel was detected in the inner 20μ of the film sealed in dilute nickel acetate solution, but the content then rose gradually and finally sharply to 1·3 wt. per cent near the outer interface. This nickel-rich plug, probably consisting of nickel hydroxide, is a feature often assumed to explain sealing in nickel acetate but has rarely, if ever, been demonstrated in detail. The nickel concentration is insufficient to indicate complete blocking by nickel hydroxide so this is partly accomplished by simultaneous hydration in all regions of the pores[5]. It might be anticipated that in the first few moments of immersion nickel ions succeed in penetrating the pores completely but are not measured in the final analysis due to their low concentration. That this is probably the case is shown by the results for the concentrated solution. Here nickel was detected throughout the film although the plug appeared to occupy about the same distance. The plug is richer in nickel but the nickel content is not proportional to the solution concentration. It should be noted that although the concentrated nickel acetate solution and the dichromate solution were of roughly comparable concentration, there is no comparison in metal contents in the inner regions of the pores. This is due to the more rapid pore closure in the nickel acetate solution preventing extensive replenishment. It was demonstrated that the nickel readings were not affected by the smearing of 'surface smudge' over the section by repetition after prolonged swabbing treatments and by showing that correct aluminium values could also be obtained. Chromium and nickel can be measured with great precision and reproducibility despite their low concentrations because this is a particularly favourable situation where heavy elements are being detected in a matrix of low atomic number.

The implications of the work should be noted. Evidently the microanalyser can provide useful information about the

composition and porosity of anodic films, and about their reaction with corrosive environments, provided they are of suitable thickness. The precision depends on the element being detected and the matrix. Clearly a particularly favourable situation is the determination of heavy elements in alumina, magnesia and silica. Regarding anodic films on aluminium alloys, determination of the aluminium content gives a measure of the porosity and should enable the concept of 'coating ratio' to be placed on a more precise basis. The influence of anodizing variables, alloy and heat treatment should now be investigated in detail. The depth of penetration and concentration of inorganic pigments containing heavy metals and possibly of metal-containing organic dyestuffs may be measured. Observations of the development of the nickel-rich plug during sealing and its subsequent removal during corrosion should throw considerable light on the mechanisms of these processes. The technique may also find some application in the study of hard anodized films and plating over anodic films. Some of these investigations are now in progress.

We thank Prof. T. K. Ross and Prof. F. Morton for providing facilities and for encouraging this work and the Department of Scientific and Industrial Research for the provision of the microanalyser and of a maintenance grant to one of us (V. J. J. M.).

ELECTRON SPIN RESONANCE OF CRYSTALLINE CHLOROPHYLL *A* AND CRUDE MIXTURES OF CHLOROPHYLL *A* WITH NORMALLY ASSOCIATED PIGMENTS

By A. F. H. ANDERSON and Prof. MELVIN CALVIN, For.Mem.R.S.
Lawrence Radiation Laboratory and Department of Chemistry, University of California, Berkeley

IN a previous communication[1] we described the preparation of a highly purified crystalline chlorophyll *a*, on which we have made some preliminary electron spin resonance observations. The electronic properties of organic solids are known to be dependent on the purity of and order in the crystals. Therefore, we shall compare the simple characteristics of the electron spin resonance signals observed in the crystalline chlorophyll *a* with those obtained from crude mixtures of chlorophyll *a* with other pigments in the form of films.

We have no detailed knowledge of the crystal structure of chlorophyll *a*, but we present two pictures to show the form of the small microcrystals (Fig. 1) and the larger microcrystals (Fig. 2). The small microcrystals which are approximately 20 Å thick are probably two monolayers interacting by their phytyl chains or by the chlorin groups and the larger crystals well ordered composites of the small microcrystals stacked together.

The electron spin resonance was carried out on an iso-octane suspension which contains a distribution of both these crystallites the optical properties of which will be described elsewhere[2]. About 0·25 ml. of a heavy suspension of chlorophyll *a* crystals in iso-octane was smeared on a small quartz plate to give a 1·5 × 0·5 cm thin film of chlorophyll *a* when the iso-octane evaporated off. The crystallinity of the chlorophyll *a* was still intact as shown by X-ray diffractometry. Illumination of the sample was carried out by passing light from a 1,000-W projection lamp through 4 cm of water to remove infrared radiation and then through a Corning 2030 filter which transmits red light from 648 to 750 mμ. The chlorophyll *a* crystals were at the same conditions as the cavity of the spectrometer. The chlorophyll *a* crystals showed a small symmetrical dark signal in the region of $g \sim 2$, with a line width of 15 gauss. Shining red light on the sample induced a symmetrical signal of $g \sim 2$ and similar line width to the dark signal, which took about 15 min to reach a steady-state intensity of about four times that of the dark signal. When the light was turned off there was a slow decay of the signal which after 10 h had not returned to the intensity of the dark signal. The shapes of the electron spin resonance signals in the dark and light are compared in Fig. 3 and the kinetics of the production and decay of the signal in Fig. 4. Two different preparations of chlorophyll *a* showed similar behaviour.

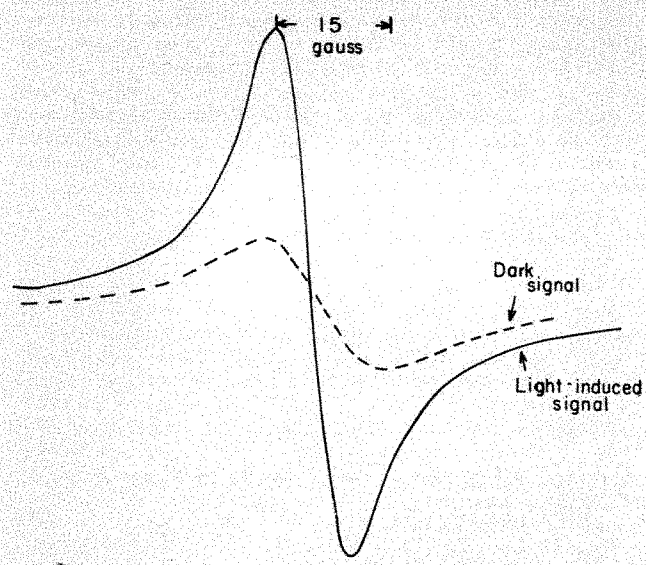

Fig. 3. Electron spin resonance signals in chlorophyll *a* crystals

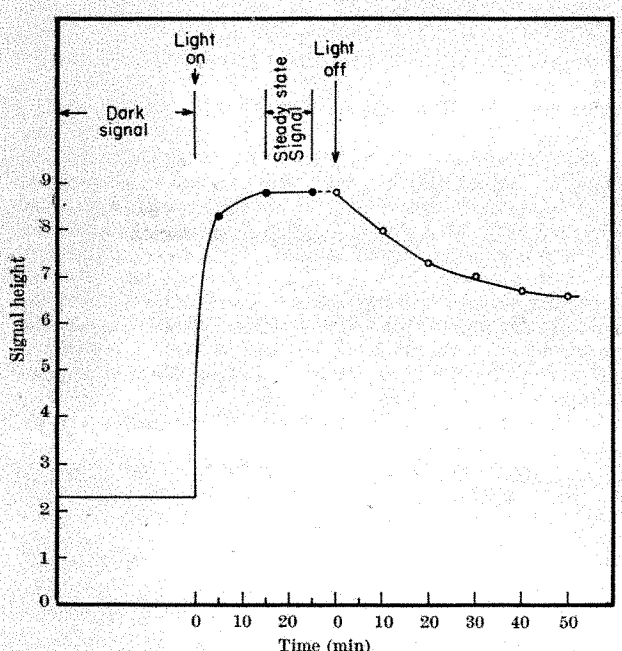

Fig. 4. Time dependence of electron spin resonance signals in chlorophyll *a* crystals

Sogo, Jost and Calvin[3] made preliminary experiments on methanol extracts of *Chlorella* algae which showed that adsorbed vapours (wet air versus dry nitrogen) on the surface of the extract were required for the production of light-induced electron spin resonance signals. We have extended these observations with the following experiment. *Chlorella* algae were washed twice with distilled water and then extracted with 100 per cent methanol at room temperature. The extract was made into samples suitable for testing in the electron spin resonance spectrometer in three ways: (1) the solvent was removed from the extract and the resultant sticky mass of pigments (chlorophyll *a* associated with chlorophyll *b*, carotenoids and quinones) was applied to a silvered copper rod; (2) the solid mass of pigments obtained in (1) was treated with 2 ml. of petroleum ether, which was then evaporated off in a cylindrical (8 mm O.D.) quartz tube to give a 0·5-mm thick and 1·5-cm long film of pigments on the bottom of the tube; (3) a phase separation of the methanol extract was carried out with petroleum ether which took up the chlorophylls and carotenes, leaving the bulk of the xanthophylls in the methanol. The petroleum ether phase was then made into a film as in (2).

Films prepared by method (1) gave only small dark signals when dry, but when treated with water vapour gave white light-induced signals; these were irreproducible in their intensities and decay times but had a constant line width of about 6 gauss.

Films prepared by method (2), where the preparation was carried out in dim light and the film had been degassed

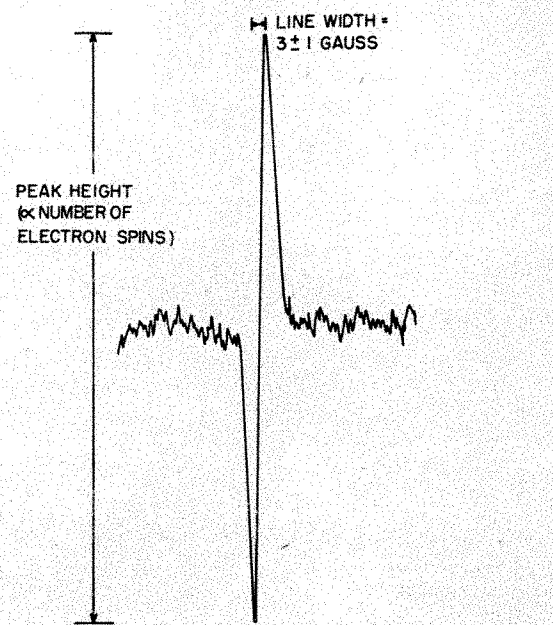

Fig. 5. Typical electron spin resonance signal from plant extract (petroleum ether)

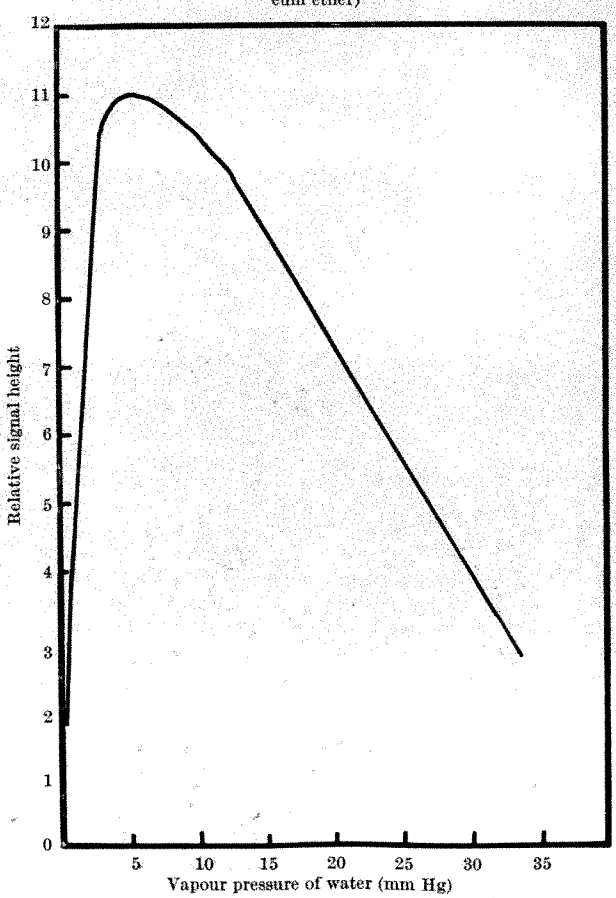

Fig. 6. Concentration of spins in an extract as a function of water vapour pressure

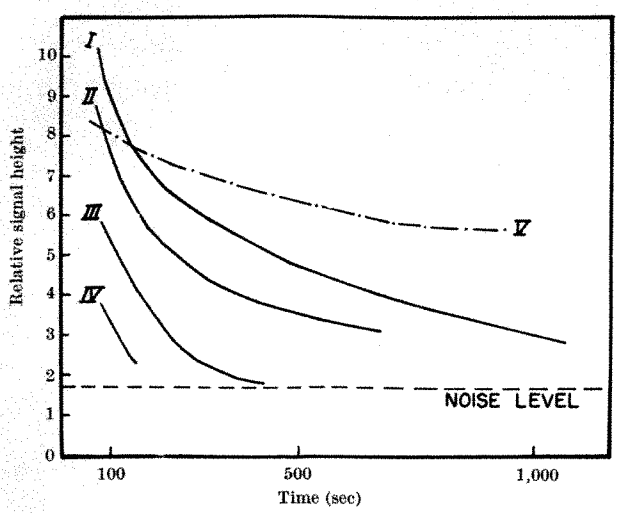

Fig. 7. Rates of decay of spins in an extract at a given water vapour pressure. I, 4·67 mm Hg H_2O; II, 14·5 mm Hg H_2O; III, 19·8 mm Hg H_2O; IV, 31·8 mm Hg H_2O

for 6 h at 10μ, gave small dark signals and white light-induced signals could not be obtained. When the same film was exposed to varying vapour pressures of deoxygenated water vapour, white light electron spin resonance signals were induced. Each addition of water vapour was carried out after the sample had been degassed and shown not to have light-induced signals. Since the line width of the signals remained constant as they decayed from their steady-state value, the concentration of spins was taken to be proportional to the signal height. A typical white light-induced signal is shown in Fig. 5; the steady-state concentration of photo-induced spins as a function of water vapour pressure in Fig. 6; and the rates of decay of the spins at given water vapour pressures shown in Fig. 7. The steady-state population of unpaired spins in the film goes through a maximum when the ambient water vapour pressure is 4·7 mm. For a given method (2) of producing the sample films, the decay rates, as shown by the slope of the curves in Fig. 7, are relatively independent of the different vapour pressures. However, a sample prepared by method (3) and with ambient water vapour pressure equal to 4·7 mm mercury, showed the equilibrium amplitude (value at $t = 0$) and the rate of decay to be markedly different from signals produced by the film (2) as shown by the curve V in Fig. 7. A solution of the extracted pigments in petroleum ether did not give light-induced signals.

It would be presumptuous to come to any definite conclusions from the two experiments described here; but they have clearly demonstrated the importance of two variables in the electron spin resonance properties of chlorophyll *a*. First, that water is necessary for the production of signals from crude chlorophyll *a*, and, secondly, the effect of purity on the signals from chlorophyll *a*. Holmogorov *et al.*[4] have also shown that water is necessary for the production of spins in preparations of chlorophylls. Because we can induce signals in crystalline chlorophyll *a* without the addition of water, we feel that water may be making small crystallites or micelles of chlorophyll *a* in the films which give rise to the signals. A similar conclusion has recently been reached by Terenin[5] to interpret the effect of water vapour on what he reported to be originally crystalline chlorophyll. The possibility that a group of water molecules might act as an electron acceptor[6] is still with us, but should be investigated on samples of chlorophyll *a* the crystallinity of purity of which are established.

The character of the signals we obtained from our crystalline chlorophyll *a* differs from those obtained by Brody *et al.*[7] using crystals prepared by a different procedure. Whereas the shape of the dark- and light-induced signal are the same in our crystalline sample, indicating the presence of one type of electron, those reported by Brody are markedly different, suggesting the presence of an impurity in his preparation (possibly xanthophyll) or different crystallinity. The light-induced signal in our avowedly impure films is much narrower (~ 3 gauss) than that produced in the crystals. These signals in the impure sample more closely resemble those seen by the other workers.

Only investigations on highly pure crystalline forms of chlorophyll *a* can be deemed significant in determining the nature of photo-induced electrons in chlorophyll *a* itself and indeed all its electronic properties.

This work was supported by the U.S. Atomic Energy Commission.

ELECTRON SPIN RESONANCE IN PHOTODYNAMIC DYES

By L. P. SIMPSON*, J. S. KIRBY-SMITH and M. L. RANDOLPH
Biology Division, Oak Ridge National Laboratory†, Oak Ridge, Tennessee

MANY organic compounds sensitize biological systems to visible light, a phenomenon known as 'photodynamic action'[1]. The photon energy is absorbed by the photosensitizer and presumably transferred by an unknown mechanism to an organic substrate, which is then destructively oxidized by molecular oxygen. Both light-induced and natural (dark) electron spin resonance signals in organic dyes and photosensitizers have been described[2–11]. The formation of unusual molecules by visible light, especially those with unpaired electrons, may be an important factor in the mechanism of photodynamic action. The properties of the dark signals are also pertinent, for the accepted chemical structures of the compounds investigated contain no unpaired electrons. There is some evidence[12,13], however, that dark signals in several cyanine, triarylmethane and phthalocyanine dyes are caused by impurities probably on the surfaces of crystals.

We have investigated the dark signals in polycrystalline methylene blue, neutral red and acriflavin (acid and neutral), in a single methylene blue crystal and in methylene blue adsorbed on activated alumina, incorporated in gelatin films and taken up on 'Amberlite *IR*-120' ion exchange resin. The effect of visible light on methylene blue was also examined.

The first derivative of electron spin resonance absorption curves was obtained using a simple spectrometer[14,15]. All but one dye were obtained from Allied Chemical Corp. Some methylene blue was obtained from the Hartman Leddon Co. and some from Matheson, Coleman and Bell. Pure 'certified' grade commercial dye was used in the initial examinations on the effects of temperature. Dye recrystallized several times in the dark from aqueous

* Present address: Rockefeller Institute, New York 21.

alcoholic solution was used to investigate the effects of temperature, the absorbed state, and light on the signals. An apparently single crystal of methylene blue was grown from aqueous solution. For work on the adsorption of methylene blue on 'Amberlite *IR*-120' ion exchange resin, the resin was purified by washings with sodium hydroxide, hydrochloric acid, and distilled water. Thin sheets of methylene blue incorporated in gelatin were obtained by dissolving the dye in gelatin solution and evaporating it to a film in air. The sheets were illuminated inside the electron spin resonance cavity with light from a 1,000-W tungsten filament lamp.

The polycrystalline dye in electron spin resonance sample tubes immersed in a water bath at 18° C was irradiated by exposure to a 200-W tungsten lamp at a distance of 6 cm. The exposure rate, determined by thermocouple measurements, was roughly 1,500 ergs mm^{-2} sec^{-1} and the effective area of 0·1-g sample about 50 mm^2.

In polycrystalline methylene blue, and also in neutral red, a singlet absorption line with a width (peak-to-peak derivative width) of about 18 gauss and a *g*-value approximately that of diphenylpicrylhydrazyl (DPPH) was observed. The methylene-blue signal remained after two recrystallizations of the dye. The dark signal in neutral red increased markedly on heating, a result also observed by Lagercrantz and Yhland[5] with methylene blue. A small electron spin resonance absorption was seen in polycrystalline acriflavin (hydrochloric acid and neutral). The signals in methylene blue and neutral red corresponded to unpaired spin concentrations of roughly $1{\cdot}2 \times 10^{18}$ and $2{\cdot}2 \times 10^{17}$ spins/*g* respectively, using DPPH as the reference material. The signals did not saturate at the micro-wave power used. The dark signal from the single methylene blue crystal showed no hyperfine splitting, although the amplitude and width of the resonance changed with orientation in the magnetic field. Some of the dark signals, but not those observed in recrystallized methylene blue, may have come from the impurities (roughly 10 per cent) in dyes as commercially prepared.

A normal dark signal appeared when methylene blue was adsorbed on activated alumina and ion exchange resin, or incorporated in gelatin. The purified resin alone showed a small signal. The appearance of the methylene blue dark signal when absorbed on the resin indicated that the cationic part of the methylene blue molecule was responsible for the signal.

The dark signal in polycrystalline methylene blue, heated or cooled in the electron spin resonance cavity, varied inversely with the absolute temperature from 84° to 423° K (Fig. 1). The non-linearity observed in this range is probably caused by changes in dielectric constant or other complications. Extensive departure from linearity was observed above 425° K, which corresponded to the melting and/or decomposition of the material. The separately measured signal at 121° K saturated at a lower micro-wave power than at 298° K. From the approach to $1/T$ dependence predicted by the Curie law, we conclude that the signal is not due to conduction band electrons, which should show no temperature dependence.

Visible light induces a signal in methylene blue adsorbed on fused silica in the absence of oxygen. This signal is quickly and reversibly quenched by oxygen[16]. We have found light induction in three other systems—polycrystalline methylene blue, methylene blue adsorbed on activated alumina and methylene blue incorporated in gelatin—and have shown that induction can occur in oxygen. Previously, light induction in oxygen was not observed, probably because of the dilute dye concentrations used.

For methylene blue adsorbed on activated alumina *in vacuo*, 4 h of illumination increased the dark signal amplitude about 25 per cent; re-admittance of dry oxygen reduced the signal to approximately its initial value. Illumination of a sheet of dyed gelatin in which no dark signal was observed elicited a small signal that saturated after about 10-min exposure, and decayed but slowly.

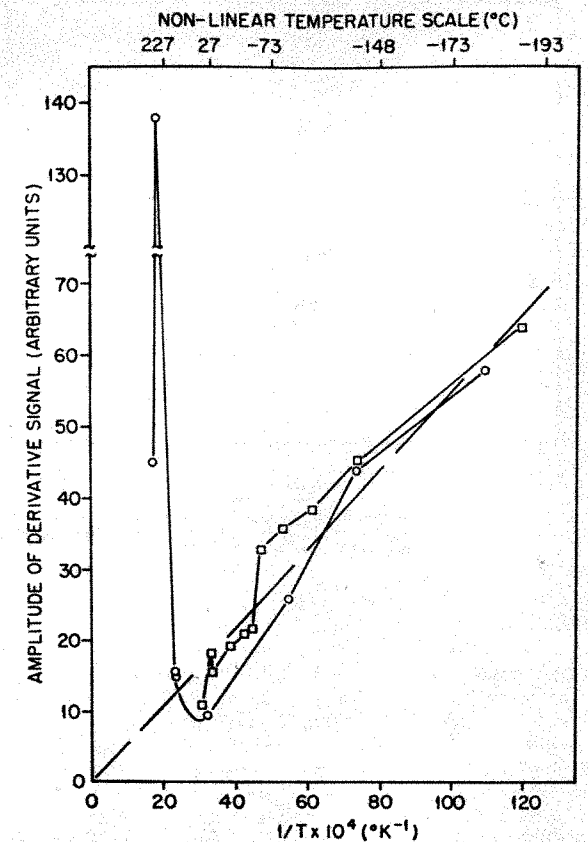

Fig. 1. Plot of polycrystalline methylene blue signal amplitudes for two samples arbitrarily normalized versus reciprocal of absolute temperature ($1/T$). The dashed lines give the $1/T$ dependence predicted by the Curie law

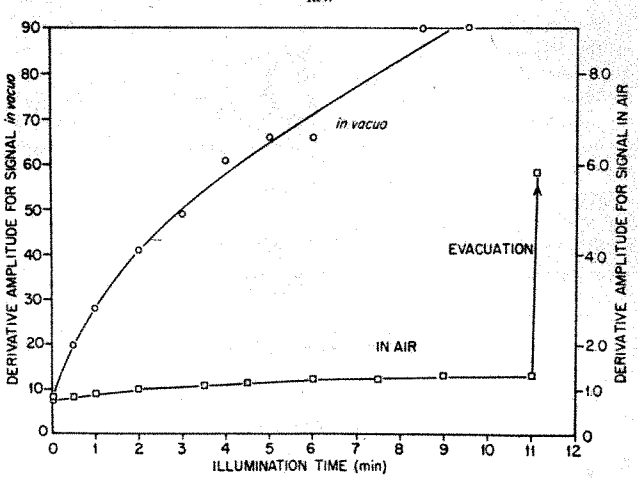

Fig. 2. Illumination of polycrystalline methylene blue in air and *in vacuo*. Note that the scale on the right for methylene blue in air is expanded ten times that on the left for methylene blue *in vacuo*

Evacuation for about 3 h multiplied the signal six times. Illumination for 13 min more *in vacuo* elicited a further increase of approximately 30 per cent. Exposure to dry oxygen produced no immediate change. Examination of separate controls revealed that no signal was produced by illumination of the alumina and gelatin alone in the *ESR* sample tubes. It was incidentally observed that visible illumination of the ion-exchange resin alone produced an increase in the small dark signal.

Results for the illumination of the dark-recrystallized dye in air and *in vacuo* are shown in Fig. 2. Evacuation of the sample illuminated in air produced about the same increase in signal as evacuation of the non-illuminated sample. The sample illuminated *in vacuo* was later

exposed to dry oxygen and no immediate effect noted. It was then kept at 96° C for 40 min in the dark: the signal increased in amplitude and decreased in line width. This heat effect thus overrides any possible annealing-out of the light-induced resonances.

Oxygen present during illumination interacts with methylene blue molecules to inhibit induction of long-lived resonance centres. If added after irradiation *in vacuo*, oxygen interacts with the abnormal molecules and quenches the apparent signal in several systems. The rate of diffusion of oxygen into the material is important for quenching and may explain the lack of immediate quenching in the gelatin and polycrystalline samples. Similar results were obtained by Kholmogorov and Terenin[21] with several triphenylmethane and xanthene dyes. However, a reversed action of oxygen has been observed for the dyes rose bengal, phloxine, and hæmatoporphyrin[7,17,21]. A possible explanation of the latter results has been proposed[21]. Some observed signals, especially in unirradiated dyes, may be those of biradicals since molecular weights are several hundred, and the accepted chemical structures have even numbers of electrons.

Our results suggest that the energy of the excited dye is transferred to oxygen, perhaps first in the photodynamic process, at least with methylene blue as the sensitizer. This conclusion can be fitted into the schemes of Schenck, *et al.*[18], Oster[19], and Kauzmann[20]. Because we have examined only the dye and oxygen in the solid-state rather than in solution with the oxidizable substrate, conclusions based on our results are tentative.

We thank Prof. H. F. Blum, of Princeton University, who suggested the original problem, and Prof. J. Turkevitch, also of Princeton for assistance. The work of one of us (L. P. S.) was supported by a grant from the U.S. National Science Foundation.

USE OF INTERFERENCE MICROSCOPY FOR THE MINERALOGICAL ANALYSIS OF SAMPLES OF AIRBORNE DUST OBTAINED WITH THE THERMAL PRECIPITATOR

By J. DODGSON
Pneumoconiosis Field Research Unit, National Coal Board

MOST of the information on the composition of coal-mining dust in the respirable size range has been obtained by chemical or spectrographic analysis of bulk samples obtained by filtration or settling. These methods cannot be applied to thermal precipitator[1] samples because insufficient dust is precipitated. The National Coal Board's Pneumoconiosis Field Research[2] is particularly interested in a method of analysis which may be applied to samples taken with the thermal precipitator, since not only is this instrument used within the Research for the systematic measurement of respirable dust concentrations, but also the technique will allow all the samples taken and stored since the commencement of the Research in 1953 to be analysed. For this reason the possibility of using phase-contrast[3–6] and dark-ground[7] optical techniques was considered; but a method using the interference microscope manufactured by Messrs. C. Baker Instruments, Ltd. (now Vickers Instruments, Ltd.) has been developed and found to be preferable. Although interference microscopy is widely used in biological investigations, it does not appear to have been previously adopted for mineralogical analysis.

Interference microscopy, like phase contrast, depends on the conversion of the invisible phase changes produced by phase-changing objects into amplitude changes, resulting in a visible intensity contrasted image of the object. The Baker interference microscope is adequately described elsewhere[8]. Briefly, the contrast is produced by a double-beam interferometer system built within the microscope and, unlike phase contrast, it does not depend on diffraction by the object. The object modifies the phase relationship between the mutually interfering double waves by an amount dependent on its optical path length. The angular phase difference so produced determines the direction of vibration of the single plane polarized wave into which the double waves are converted. This enables the intensity of the transmitted wave to be controlled with a goniometer analyser.

The mineralogical analysis of thermal precipitator samples is based on the combination of interference microscopy and the well-known dispersion staining phenomenon[9]. The mineral particles are immersed in a highly dispersive fluid thickened with pyroxylin to avoid disturbance of the dust deposit on the cover-glass. If the embedding fluid is more highly dispersive than the mineral and the dispersion curves of fluid and mineral intersect, coloured images are formed in white light by interference microscopy. The order of interference is determined by the phase relationship between the double beams which, in these experiments, was adjusted (by inclusion of a unit retardation plate with the standard quarter wave-length birefringent compensating plate) to give colours similar to those normally experienced with phase contrast and dark-ground techniques. The colours themselves do not depend on the absolute values of refractive indices but mainly on the relative slopes of the dispersion curves of fluid and mineral and on their point of intersection, provided that the particles are not too thick. They may be varied by orientation of the analyser. This may be set to reduce the intensity of those wave-lengths producing either positive or negative angular phase differences between the fluid and mineral particles or for zero phase difference (that is, at the point of intersection of the dispersion curves); the angular phase difference, θ, is given by:

$$\theta = \frac{t\ (Nf - Np)\ 360}{\lambda}$$

where t is particle thickness, Nf and Np the respective refractive indices of fluid and particle and λ the wave-length of the illuminating light.

Fig. 1 represents the dispersion curves of quartz, kaolinite and muscovite in a fluid composed of orthophthalic acid dibutyl-ester and cinnamic aldehyde ($Nd = 1{\cdot}558$). In the range of wave-lengths where $Np > Nf$ the light is retarded by the particle and its intensity may be reduced by crossing the analyser for negative phase differences to produce positive contrast colours. The proportions of light of these wave-lengths in the particle image depend on the slope and point of intersection of the dispersion curves. Thus, for equal refraction at the red end (for example, quartz), the longer wave-lengths, where $Np > Nf$, are eliminated or reduced most and the blue-yellow wave-lengths, where $Nf > Np$, least. The result is a pale-blue particle. For equal refraction towards the violet end (for example, muscovite), light of all visible wave-lengths is reduced in intensity, with violet being reduced least, giving a dark blue particle. The opposite applies if the analyser is crossed to reduce the intensity of the wave-lengths causing positive angular phase differences (that is, $Nf > Np$), yellow or red negative contrast colours then being obtained, due to the greater reduction in intensity of the blue or blue-yellow wave-lengths transmitted by the particle. Similarly, by setting the analyser for zero phase difference (that is, $Nf = Np$), a third series of colours is obtained on a dark background, the colours depending on the wave-length at which the dispersion curves intersect. The colours produced by quartz, kaolinite and muscovite in the foregoing fluid are shown for each contrast position in Table 1. Other silicates such as montmorillonite and illite give similar colours to muscovite and, generally speaking, cannot be optically distinguished from it. The presence of carbonates, pyrites and coal particles does not interfere with the analysis.

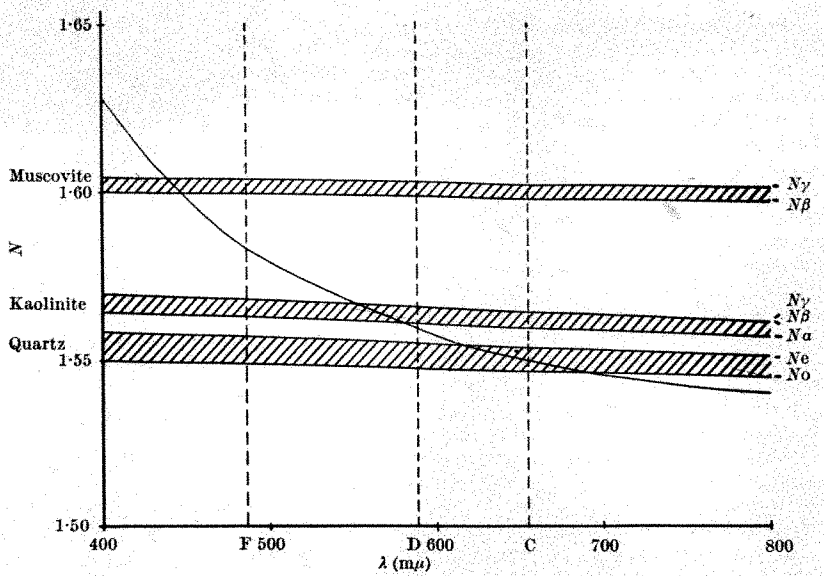

Fig. 1

Size analysis down to 1μ is possible if a 4-mm 'double focus' $N.A.$ 0·7 objective is used together with a low-voltage tungsten filament lamp, such as the Baker 'Intense Lamp', adjusted for Köhler illumination. A binocular attachment fitted with × 10 eyepieces ensures comfortable viewing conditions.

Table 1

Mineral		Interference colours when analyser set for :		
		Positive contrast	Central dark ground	Negative contrast
Quartz		Pale to light blue	Clear blue	Dark red
Kaolinite		Royal blue	Red-orange	Pale orange-yellow
Muscovite	Orientation of basal pinacoid parallel to support	Dark blue-grey	Yellow-orange	Yellow
	Orientation of basal pinacoid normal to support	Dark blue-grey to light blue	Blue to orange-red	Orange-yellow

* Figures in brackets are corrected mean values with Sample No. X1072 taken = 100 per cent.

The effect of thickness has been investigated empirically by the examination of pure mineral samples. Increasing thickness in particles of projected diameter of 1–20μ merely results in increased contrast and depth of colour, but the basic colour does not alter. Particles exceeding about 20μ projected diameter may show reversal of contrast due to the angular phase difference exceeding 180°. Changes in colour occur, but these are not sudden since only certain wave-lengths are affected at first. It is often possible to identify a particle of 50μ projected diameter; but, to reduce the risk of error, the method should be limited to particles of less than 20μ projected diameter.

Birefringence is unimportant in the case of quartz and kaolinite. Reversal of contrast may occur with small mineral particles of strong birefringence such as muscovite orientated with the basal pinacoid normal to the support. The effect is easily noticed and may be controlled to some extent by slight rotation of the analyser.

The most important advantage of interference microscopy is the ease with which one may switch from one contrast position to the other. This provides the equivalent facility to the use of both positive and negative phase contrast and dark-field microscopy, and is particularly useful where subjective assessment of colour difference is involved. Furthermore, the intensity of the interference colours in each contrast position may be controlled by the analyser, a valuable asset when studying particles of varying size. The design of the instrument permits use of the full aperture of the substage illuminator and so avoids the disturbing 'halo' or diffraction effects common to phase-contrast and dark-ground microscopy.

The assessment of the reliability of the method is made difficult by the need to compare number count data with the more usual mass units. Without accurate knowledge of the shape-density factor variations between different minerals, comparison of optical analytical methods with chemical or spectrographic analysis of similar samples cannot be very satisfactory. Nevertheless, mixed samples of 'pure' quartz, kaolinite and muscovite of known composition by weight, supplied by the Safety in Mines Research Establishment, and previously used by them to determine the accuracy of quartz evaluations of respirable dust[10], have been analysed for this purpose. The results are shown in Table 2, where the number/size counts obtained by the interference microscope have been converted to percentage volume, assuming no difference in shape-density factors between the minerals. The agreement is considered to be reasonably good, bearing in mind the limitation of this kind of comparison. It is worthy of note that the presence of an appreciable quantity of muscovite (samples *X*2479 and *X*2480) seems to depress the estimates of quartz and kaolinite. This suggests that the shape-density factor of muscovite may be materially different from those of quartz and kaolinite.

I thank Mr. F. N. Smith of Messrs. Baker Instruments, Ltd. for advice, and Dr. G. Nagelschmidt of the Safety in Mines Research Establishment for providing the mineral samples.

MESOMORPHIC AND CRYSTALLINE STATES IN POLYVINYL CHLORIDE BY X-RAY DIFFRACTION

By Dr. M. MAMMI
Centro Nazionale di Chimica delle Macromolecole del C.N.R., Sezione di Padova
AND
Dr. V. NARDI
Istituto Nazionale di Fisica Nucleare, Università di Padova

THE presence of a large fraction of molecular chains in mesomorphic states inside stretched fibres of polyvinyl chloride, as for other polymers, increases the difficulties, always great, to determine within reasonable error the amount of the crystalline fraction by X-ray analysis. It is interesting, therefore, also in order to simplify these determinations and to make the results more reliable, to collect information on the molecular arrangement inside the non-crystalline fraction, the determination of the chain arrangement inside the crystallites having already been carried out[1].

The present analysis is based on the behaviour of the crystallites and of the free chains, that is, the chains not ordered in a three-dimensional network, during the shrinkage of previously oriented samples of polyvinyl chloride.

The behaviour was followed experimentally on the X-ray diffraction patterns from a completely oriented sample *A*, and from samples *B*, *C*, *D*, which were obtained by progressive shrinkages of *A*.

The typical diffraction spectra obtained (with copper $K\alpha$-radiation) from non-oriented samples of polyvinyl chloride (mean mol. wt. about 60,000; Montecatini production) are shown in Fig. 1*a*, for a completely amorphous sample—or at least with crystalline amount that should not exceed a few unit percentage, on the basis of its chemical preparation—and in Fig. 1*b* for a sample with rather large value of crystallinity (about 20–30 per cent in weight).

Two maxima appear in Fig. 1*a* which are usually indicated as amorphous diffraction[1]. The external maximum, due to a close arrangement of groups of atoms at Van der Waals distances, is at 3·6 Å, near the amorphous maximum present in most of the polymers at about 4·0 Å (ref. 2)—and the internal maximum, due to a free chain arrangement in which larger distances are preferred, is at 5·0 Å. In Fig. 1*b* considerable contributions of crystalline reflexions are present also in the peak at 3·6 Å.

Quite different spectra are obtained in the case of very strong orientations of free chains and crystallites along the fibre axis. The X-ray photograph from a 500 per cent stretched fibre (sample *A*) is given in Fig. 2*a* and the intensity on its meridional radius is shown by the photometer plot in Fig. 1*c*. The maximum at 5·0 Å is completely absent as are the equatorial (200) and (110) reflexions, while an external maximum appears centred at 3·8 Å. This value does not depend on any reasonable choice for the subtraction of the background. Since fibre is strongly oriented, no polar crystalline reflexions of this spacing may contribute on the basis of the assumed structure[1].

On the contrary, the photometer plot along the equator (Fig. 1*d*) shows strong reflexions (200) at 5·20 Å, (110) at 4·72 Å and (210) at 3·70 Å, besides others.

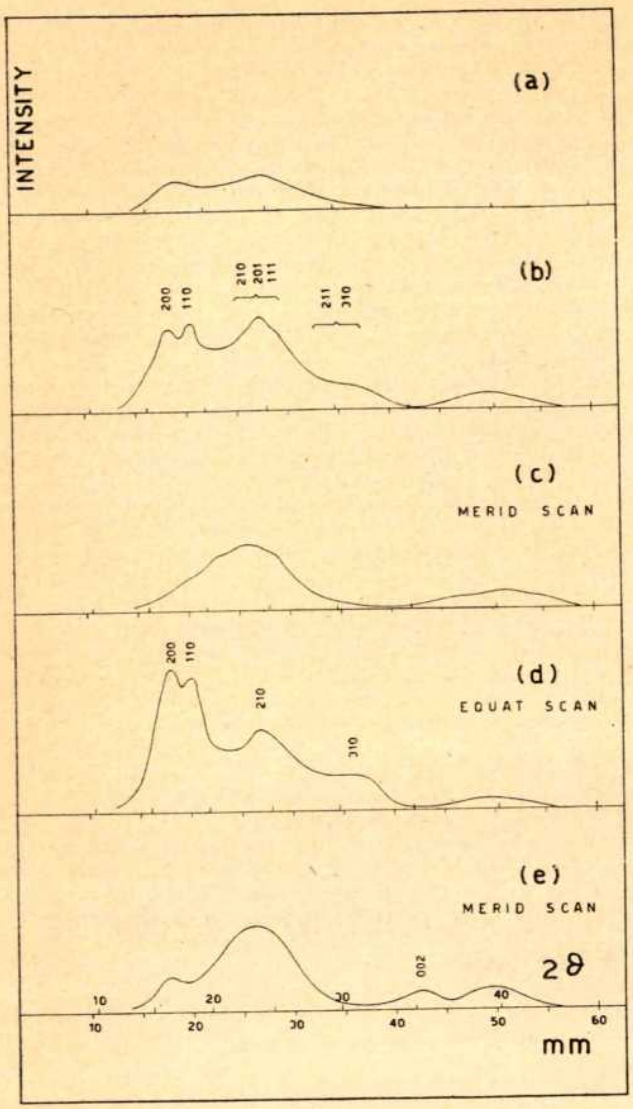

Fig. 1. X-ray diffraction spectra for samples of polyvinyl chloride. *a*, Geiger registration by amorphous polyvinyl chloride (ref. 1). The used angular scale is linear in tan 2θ. The intensity scale of (*a*) is not the same arbitrary scale of (*b*), (*c*), (*d*), (*e*), obtained by photometric registrations of films. *b*, Not-oriented crystalline sample. *c*, and *d*, 500 per cent stretched fibre (sample *A*). *e*, Shrunk fibre previously stretched (sample *C*)

A peculiarity of this oriented sample is the value I_{200} of the apparent intensity of the (200) reflexion, which is systematically larger than the corresponding value of I_{110}. This situation disagrees with the theoretical value $\frac{I_{200}}{I_{110}} = 0{\cdot}20$, and differs from that in Fig. 1*b* characteristic of non-oriented samples.

Interesting information can be obtained by analysing the X-ray patterns of fibres which are all initially stretched like sample *A* and afterwards shrunk in water for a fixed time at different temperatures T_s above the glassy transition point T_g. For $T_s = 85°$ C (sample *B*; reduction in sample length 31 per cent, Fig. 2*b*) the crystalline reflexions show an almost unchanged orientation, compared with Fig. 2*a*, and the equatorial arc (200) appears with the same length of the arc (110). Besides these strong reflexions a new complete ring, sharp enough to be compared with a crystalline reflexion, becomes clearly observable with a maximum of intensity at $5{\cdot}4_6$ Å (Fig. 2*b*). Sharpness, position and intensity of this ring were carefully evaluated by means of many radial scannings, each forming a different angle χ with the film polar radius. The intensity I_M of the maximum observed on these scannings between 4·0 and 6·0 Å (always taken as unresolved) versus increasing values of χ is shown in Fig. 3; the estimated position of this unresolved maximum is also indicated.

A remarkable fact revealed by these scannings is the sudden shift of the position of I_M from 5·4 to 5·0 Å at $\chi \simeq 40°$ and from 5·0 back to 5·4 Å at $\chi \simeq 140°$. As shown by Fig. 3, I_M is maximum on the equatorial radius ($\chi = 90°$) and decreases until χ reaches the limiting values of the interval 40°–140°. Outside this interval, I_M appears to be constant.

Since the high orientation of the crystallites, the main contribution to the intensity I_M for $40° \leqslant \chi \leqslant 140°$ certainly comes from the reflexions (200) and (110), even if some amorphous diffraction should be considered.

Other noteworthy facts that emerge from the analysis of shrunk samples are that for any value of $T_s > T_g$, the apparent value measured along the equator of I_{200} becomes smaller than I_{110}, and the arc-length of the (200) reflexion remains equal to the (110) arc-length at any stage of the disorientation, with unchanged spacings as in Figs. 1*b* and *d*.

Furthermore, the crystallite disorientation increases with T_s so that the reflexion condition $\varphi > \theta_{002}$ for (002) may be satisfied by many crystallites if T_s is large enough ($\theta_{002} = 17°\ 28'$ is the Bragg angle of this reflexion and φ the angle between the crystallite *c* axis and the fibre axis). For $T_s = 107°$ C (sample *C*: reduction in length 55 per cent) the reflexion (002), not yet observable for the sample *B*, reaches the maximum value of intensity. It appears as a polar arc, beside the maximum at 3·8 Å, the ring at 5·4 Å and other crystalline reflexions which are still oriented. The meridional scannings of the X-ray photograph obtained by sample *C* is shown in Fig. 1*e*.

For larger values of T_s the intensity of (002) decreases again. For a completely disoriented fibre (sample *D*, obtained by shrinkage at 150° with recovery of the sample length before stretching) the intensity is distributed on a complete ring and this reflexion is no longer detectable.

From the previous review of experimental data, it follows that the main points to be explained are: (1) the appearance above T_g of the continuous ring with spacing 5·4 Å; (2) the reasons, in terms of molecular arrangements, of the position of this ring, different from the maximum at 5·0 Å of Fig. 1*a*, and different with some evidence from the position of any classified crystalline reflexion from polyvinyl chloride[1,3].

By comparison of Fig. 1*a* with Fig. 1*c* it can be concluded that the chain arrangement responsible for the internal ring in Fig. 1*a* may be oriented like a crystalline arrangement. In order to explain the appearance of the complete ring at 5·4 Å for T_s immediately above T_g

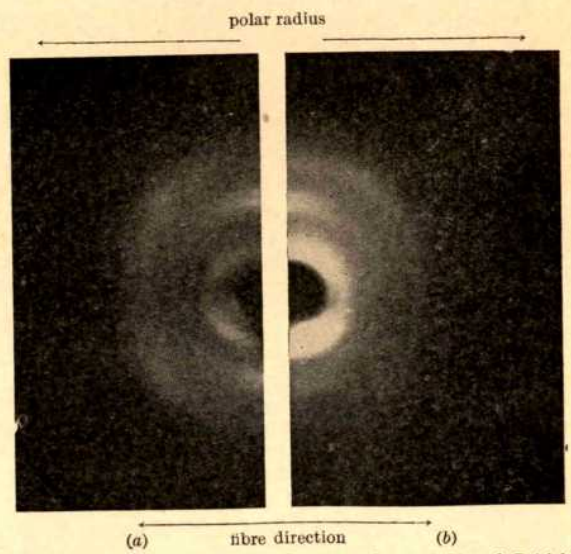

Fig. 2. X-ray patterns obtained from samples *A* (left) and *B* (right)

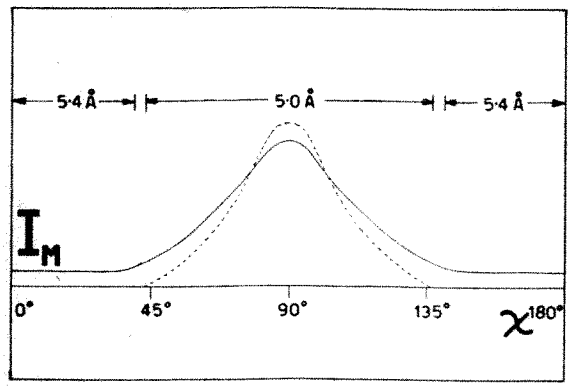

Fig. 3. Largest intensity value I_M for the unresolved maximum between 6·0 and 4·0 Å as function of χ. The spacings corresponding to the Bragg angles of I_M are also indicated. – – – spectrum obtained by sample *A*; —— by sample *B*

(sample *B*), a first picture could be based on a non-random disorientation of the crystallites of smallest dimensions apparently concerning only the (200) reflexion. If this is the case, one should assume, of course, a variation of the network spacing of 5·2–5·4 Å, due to very strong stresses or leaks in regularity of the polymer chains and tolerated by the network through dilatation of the cell.

A variation of 0·2 Å in the (200) spacing appears to be of the same order of magnitude as the differences in the experimental determinations reported in the literature[1,3]—also the value 5·39 Å instead of the theoretical value d_{200} = 5·20 Å has been observed[1]—but it appears extremely large if compared with the observed cell variations in other polymers; for example, not larger than 0·06 Å in polyethylene[4]. This variation in spacing, not dependent on any reasonable choice for background subtraction, must be considered particularly significant in our case, because it is also observed on the same X-ray photograph through different radial scannings. On the other hand, it largely exceeds any statistical deviation of the experimental determinations on many samples. Moreover, since the arc-length of the (200) and (110) reflexions from large-size crystallites are observed to increase both of the same amount by increasing T_s, one would also expect accordingly to observe in sample *B* (Fig. 2*b*) a second complete ring corresponding to the (110) reflexion.

To explain the absence of this ring, it should therefore be assumed that the modalities of this non-random disorientation vary with the size of crystallites.

It is worth noting that while the absence in sample *B* of a (002) reflexion from disoriented—small size—crystallites may be justified in the same way as for sample *D*, the same explanation cannot hold for the (110) reflexion.

We believe that a different explanation must be given to the appearance of the ring at $5{\cdot}4_0$ Å in the first stage of disorientation, avoiding the assumptions already mentioned.

It may be observed that the sudden shift of the position of the maximum intensity I_M at $\chi = 40°$ and at $\chi = 140°$ (Fig. 3) allows us to classify the oriented chains in the stretched fibre in two different groups. One group belongs to crystallites, with spacings independent of the orientation. These, even above T_g, become disoriented only with difficulty, thereby showing relevant friction forces associated with their displacement. A second group, having a very ordered arrangement, as the polar spectrum in Fig. 1*c* shows, becomes disoriented with the same facility that should characterize the oriented free chains which are certainly present in the fibre.

We classify these chains as being in a mesomorphic (nematic) state. The position of the ring at 5·4 Å can now be easily justified. In fact, a variation in the preferential spacing of mesomorphic chains with the state of the sample—for example, 5·0–5·4 Å as may be deduced from the comparison of the spectrum given by *B* or *C* with the one in Fig. 1*a*—becomes quite acceptable, since the intensity of the mean field of the forces acting on them is certainly less than the intensity of the crystalline field.

In the projection on the *ab* plane of the crystal cell, each chain appears[1] to be surrounded by four first nearest neighbours at a distance of 5·3 Å. It is therefore justifiable to hold that for iso-oriented chains not ordered in a three-dimensional network, the preferential distance is larger than 5·3 Å, with a small dispersion because of the strong C—Cl dipole–dipole interaction. This explains the rather sharp definition of the observed ring at $5{\cdot}4_0$ Å.

A second way to account for the differences between the position of this non-crystalline ring and the internal maximum in Fig. 1*a* is to consider an appreciable contribution in the last one of the (200) and (110) reflexions, both described by a very spread-out gaussian and superposed with an amorphous maximum, placed at 5·4 Å for any sample. In the last case, one should then admit even for the maximum at 3·6 Å in Fig. 1*a* an appreciable contribution of the crystalline reflexions (for example, 210, 201, 111), and the real position of the external amorphous maximum could therefore lie at a smaller value of θ. As required by the meridional scannings of the X-ray photographs (Figs. 1*c* and *e*) the correct position is 3·8 Å. This position is closer to diffraction maximum shown by the liquid monomer, which we have observed at 4·17 Å. An external amorphous maximum with near the same position of the corresponding liquid monomer maximum is in agreement with the known results of Katz concerning many different polymers[2]. From all the analysed spectra, this maximum does not show any orientation with fibre stretching. This interpretation of the spectrum in Fig. 1*a* that we consider the most reasonable requires, however, the presence of a crystalline percentage of about 10 per cent in the corresponding sample.

Experimental results so far obtained, completed by the shrunken samples technique reported here, does not give sufficient information to define with less uncertainty the chain arrangement inside polyvinyl chloride fibres. Improvements could perhaps be obtained by applying different techniques, like nuclear resonance or neutron diffraction by deuterated samples.

With the choice of the internal amorphous maximum at $5{\cdot}4_0$ Å, accurate measurements of variations in the crystalline amount for oriented unshrunk fibres are possible. On the basis both of this choice and of the assumed peak symmetry, one can separate the (200) and the (110) reflexions from the maximum due to the free chains without an extraordinary number of assumptions. By using the integral intensities of these reflexions, measured on the photometer equatorial plot, the variations of the quantity:

$$\frac{I_{200} + I_{110}}{I_{\text{mes}} + I_{200} + I_{110}}$$

give with good approximation the numerical values for the variations in crystalline fraction weight.

We have applied this method to fibres in which the crystalline fraction was increased by ultrasonic radiation (1 Mhz), keeping the orientation unaltered to the same degree for all the samples[5]. The variations determined in the crystalline fraction (even for a few unit per cent) were in agreement with the behaviour of the physical properties (for example, the values of breaking load, swelling, etc.) as required by well-known empirical relations[6].

Of course, the determination of absolute values needs a 'calibration' by means of a sample of known composition.

AN INDICATION OF UNDERWATER SOUND PRODUCTION BY SQUID

By ROBERT T. S. IVERSEN
U.S. Bureau of Commercial Fisheries, Honolulu, Hawaii
PAUL J. PERKINS
Narragansett Marine Laboratory, University of Rhode Island, Kingston
AND
RICHARD D. DIONNE
U.S. Naval Submarine Base, New London, Conn.

IN recent years there have been many investigations of underwater sound production by marine animals and of the role of such sounds in animal behaviour. Most of this work has been focused on fish and mammals, and to a lesser extent on invertebrates.

The purpose of this communication is to present additional evidence of underwater sound production by marine squids. Several authors[1-3] have reported sound production by squids which were out of the water, but Nishimura[4] was the first to report on sounds produced underwater by squids. These sounds were recorded near trap nets in coastal waters off Atami City, Japan, and were called 'swimming noises' by Nishimura.

The underwater sounds reported here were tape-recorded aboard the U.S. Bureau of Commercial Fisheries research vessel *Hugh M. Smith* on November 3, 1958, at a night-light station (2130–2230 h) at position 2° 02′ N., 150° 07′ W. There was no wind, the sea surface was completely calm except for an occasional gentle swell, and the moon was not shining. A 200-W light was submerged 60 cm below the sea surface. A directional microphone mounted in a waterproof metal container was attached to the end of an 8-ft. aluminium handle. The microphone had a frequency response flat of approximately 300–5,000 c/s and an impedance of 25–50 ohms; other details are unknown. The observer manipulated the handle to train the microphone on squids in the water. The microphone housing was submerged about 1 m. Wiring from the microphone passed through a watertight connexion linking the aluminium handle and the microphone housing, up the hollow handle, and to a 'Magnecord *PT6–BN*' recorder operating at a tape speed of 7·5 in/sec. Comments by an observer were included on the same tape. The recorded sounds were graphically portrayed by a Kay 'Vibralyzer' sound spectrograph. Fig. 1 shows the entire frequency spectrum recorded. The recording shown in Fig. 2 was first passed through an Allison model 2*A* band-pass filter, which eliminated frequencies below 300 and above 2,400 c/s. No attempt was made to measure loudness of the sounds when originally recorded.

The squids, in groups of 10–20 individuals, swam rapidly in and out of the area illuminated by the night-light. Individual squids approached within 1 m of the microphone, and groups often passed beneath the microphone at a depth of 3–5 m. Squids of three species were captured by dipnet during the night-light station: one *Thysanotheuthis rhombus* Troschel—dorsal mantle-length 154 mm; one *Symplectoteuthis oualaniensis* (Lesson)—dorsal mantle-length 151 mm; and three *Onychoteuthis banksii* (Leach)—dorsal mantle-lengths 44 mm, 45 mm, and 65 mm. Squids observed near the microphone during sound recording were estimated to be about 150 mm in dorsal mantle length and were probably either *T. rhombus* or *S. oualaniensis*. Other animals, such as myctophids and flying fish, were also attracted to the night-light, but the recorded sounds were not noted when they were nearby.

The recorded sound burst shown in Fig. 2 was approximately 1·2 sec in duration and included 33 individual sound pulses. Time-intervals between pulses increased from 31 to 48 msec during the sound burst. The number of pulses ranged from 28 to 47 in six sound bursts analysed in this manner. To the human ear, sounds of the squids were a faint, rapid popping sound. Bartsch[3] also reported hearing popping sounds produced by squids, but by squids the speed of which had carried them clear of the water.

The recorded sound energy was concentrated above 1,500 c/s (Fig. 2), but since the darkness of the spectrogram reflects the 'Vibralyzer' dial settings, comparison of the intensities is only relative. The lower frequencies of the pulses reach 500 c/s; but here they are largely masked by what is probably machinery noise from the vessel, centred at 500 c/s. Sounds of squids recorded by Nishimura[4], analysed with a panoramic sound analyser, contained frequencies of 1,000–4,000 c/s. He recorded peak intensities at approximately 1,500 c/s, with the intensities dropping sharply above 1,500 c/s.

Voice comments recorded concurrently with the underwater sounds indicate that in the majority of cases squids were near the microphone when the sounds in question were recorded. For example, during one 30-min recording period, the observer noted the presence of squids near the microphone in 10 of 16 instances when sounds were recorded. The sounds were not always picked up even while squids were near the microphone. This suggests that sounds were produced sporadically by individuals, perhaps incidentally to abrupt changes in speed or to radical manœuvres.

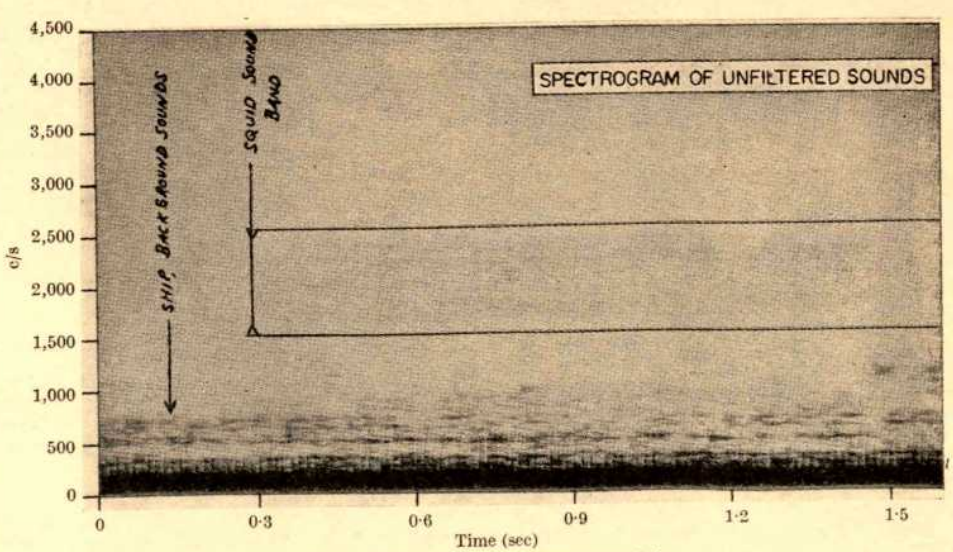

Fig. 1. Entire frequency spectrum recorded

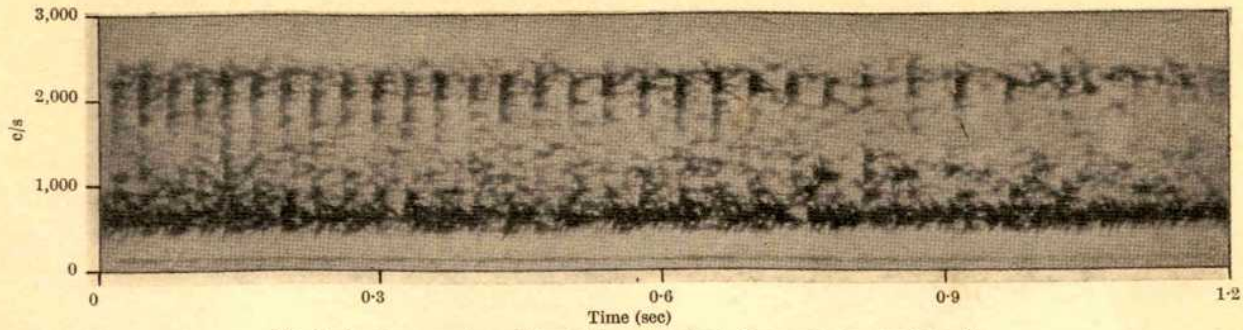

Fig. 2. Spectrogram of sound burst thought to have been made by oceanic squid

The following hypothesis is offered to explain how these sounds are produced. The sounds may result from fluttering of the thin external lips of a squid's siphon while water is being ejected through the siphon from the mantle cavity. When the expulsion (or ejection) of water begins, pressure in the siphon would be greatest and the lips would flutter more rapidly than at the end of the ejection, when the water pressure in the siphon would be lower. This would account for the increasing interval between sound pulses in Fig. 1. The process is analogous to that which occurs when a small rubber balloon is filled with air and then released. As the air escapes, the neck and lips of the balloon flutter and a series of sound pulses are produced, decreasing in frequency as the air pressure within the balloon decreases.

The foregoing hypothesis was suggested because of the lengthening intervals between pulses towards the end of the sound burst. It is possible, however, that the bursts are some other swimming sound of the squids. In this regard, Figs. 1 and 2 are similar to a spectrogram recorded by Moulton (reported in ref. 5) of the swimming sounds of several million anchovies (*Anchoviella choerostoma*). This spectrogram also depicts short pulses of sound as vertical bars, but the bars are more irregularly spaced and show frequencies approaching 5,000 c/s.

The hard beaks of the squids should also be mentioned as possible sound producers. On one occasion while squids were nearby, a faint snap was heard instead of the usual popping sound.

We thank Dr. William N. Tavolga for advice.

CORRELATION OF WIDELY SPACED MAGNETIC PROFILES IN OCEANIC AREAS

By Dr. D. H. GRIFFITHS and R. P. RIDDIHOUGH
Department of Geology, University of Birmingham

DURING the interpretation of total field magnetometer observations from the Scotia Sea we were concerned with utilizing to the full the information from sets of more or less parallel traverses several hundred miles long, separated by distances of as much as 50 miles. Such separations clearly precluded the correlation of individual magnetic features between tracks, but visual inspection suggested that in places correlation on the basis of the general magnetic character of sections of traverse might be possible. A method was therefore devised by means of which it has been found possible to divide up traverses into sections of different character. In general these sections can be correlated from traverse to traverse, thus enabling a map of the region to be built up which it is believed may have some geological significance.

The regional gradient was removed and the choice made of magnetic features suitable for measurement. These were usually well-defined features with a total amplitude of greater than about 40γ, and of horizontal distance between positive and negative peaks of less than 16 miles. Three measurements were made on each feature. These are shown in Fig. 1. u is the peak to peak amplitude, v, half the horizontal distance between the points of half-maximum gradient, and w, the horizontal distance from the positive peak to the curve taken at half the vertical distance between peaks. The traverses to be discussed in detail have a north–south direction, and the measurements of v and w were always made on the south side of the positive peak.

For each traverse three separate graphs are drawn showing the variation of u, v and w with distance, and two others of the changes $\delta u/\delta v$ and $\delta w/\delta v$ with distance, where δu, δv and δw are the differences along the tracks between consecutive values of u, v and w. The use of a third possible relationship, the variation of $\delta u/\delta w$ with distance, has been found to be superfluous as in practice it provides no additional information of value.

The division of the traverses into sections is carried out by inspection in the following way. Over certain lengths of track there is an obvious similarity in the variation of the three indices; over other lengths only two indices may show any visible correlation, and there exist also stretches where all three are apparently unrelated. The points at which changes in the nature of these mutual relationships occur are taken as boundaries. Although most of the main divisions could be made by careful inspection of the graphs of u, v and w, the two subsidiary graphs are used to assist their recognition and make the process more objective.

The division into groups having been visually established as described, the probability levels of the correlation coefficients r_{uv}, r_{vw} and r_{uw} for each section of track are determined. These levels are used to classify the sections into the categories listed in Table 1.

The various traverses, plotted in their proper positions and divided into sections, are now inspected. Where appropriate, the boundaries are extended from track to track, thus defining regions of different magnetic type.

It must be emphasized that this method does not depend on the various correlation coefficients reaching a high level of significance. Probability levels merely serve to define magnetic types, and it is the various types which are

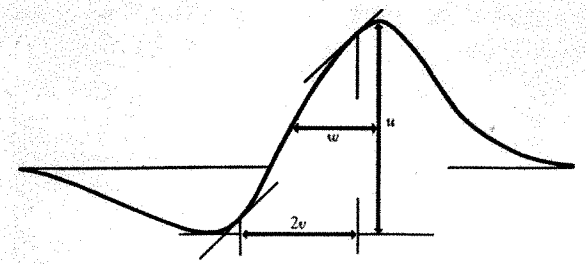

Fig. 1. Magnetic feature showing the indices u, v and w

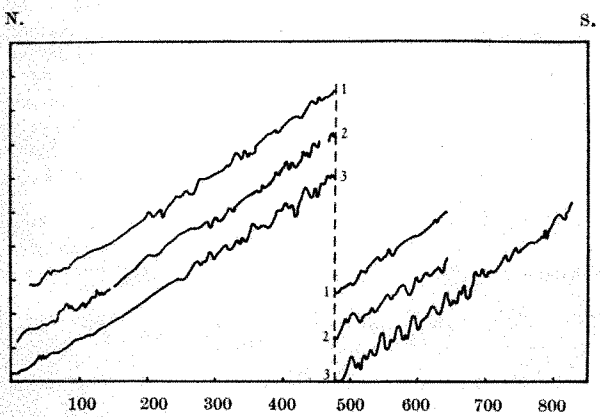

Fig. 2. Total magnetic field profiles across the Drake Passage. The vertical intervals are thousands of γ. The horizontal scale represents distances in nautical miles from Port Stanley

used in correlation from traverse to traverse. The numerical values of the levels, that is, 10 and 15 per cent, were chosen from observations so as to give a wide range of types in the area studied.

To illustrate the use of the technique three traverses from the Drake Passage area of the Scotia Sea, where the depth of water is fairly constant at about 2,000 fathoms, have been taken as examples. These are given in Fig. 2. They run approximately in a north-to-south direction and are numbered 1–3 from east to west. Apart from the magnetically undisturbed area in the north the traverses show no obvious features which can be used for correlation.

In Fig. 3 are plotted the values of u, v, w and $\delta u/\delta v$ and $\delta w/\delta v$ for Track 3. On this track the most obvious feature of the upper three graphs is a section of type A between 50 and 250 miles south of Port Stanley. South of this u, v and w show a recognizable similarity of variation until the vicinity of 550 miles is reached, where there is a sharp rise in all three values. The average rise in u at this point continues until 685 miles, and over this section there is no significant correlation of u with v or w. At 685 miles the value of u decreases again and the marked correlation between u, v and w reappears. From the lower two graphs it can be seen that there is also a change of character at 320 miles. The visually observed division in the vicinity of 550 miles can now be defined rather as a separate transition zone with limits at 510 and 580 miles. Calculation of the various correlation coefficients then determines the types of the various sections, these being marked on the diagram. Tracks 1 and 2 can be similarly divided, the sequence of sections being similar,

Table 1

Category	Probability levels of correlation coefficients (%)		
	< 10	< 15	> 15
B_1	$r_{uv}\ r_{vw}\ r_{uw}$		
B_2		$r_{uv}\ r_{vw}\ r_{uw}$	
or	any two		
C_1	r_{vw}		$r_{uv}\ r_{uw}$
C_2		r_{vw}	$r_{uv}\ r_{uw}$
D_1	r_{uv}		$r_{vw}\ r_{uw}$
D_2		r_{uv}	$r_{vw}\ r_{uw}$
E_1	r_{uw}		$r_{uv}\ r_{vw}$
E_2		r_{uw}	$r_{uv}\ r_{uw}$
F			$r_{uv}\ r_{vw}\ r_{uw}$

A_1, no magnetic features; A_2, less than 1 feature per 75 miles; G, areas of very narrow magnetic features of high frequency per mile (confined to shallow water areas).

but differing in some respects. Correlation of the three tracks is shown diagrammatically in Fig. 4. The area of type A_1 is well defined on all three, being bordered on the north side by an area, or areas, which are somewhat indeterminate owing to sparsity of data. To the south of the type A area all three tracks cross a B type area of considerable size, although there is a small region of type C_2 on Track 1 in the north-eastern corner. The southern margin of the B type area is clear, and beyond this lies a region which is marginally of F type and which grades into one of C_2 type in the east. The most southerly parts of all the tracks have very little in common, this being provisionally interpreted as indicating that the type boundaries have a trend roughly parallel to the traverses.

The correlation of only three traverses has been described, the purpose being to demonstrate the method, not to produce a structural map. Interpretation of other traverses crossing the Drake Passage region does in fact confirm and extend the main boundaries already defined. Five traverses, similarly widely spaced, have also been made in an east–west direction between the Falkland Islands and South Georgia. In this region it has also

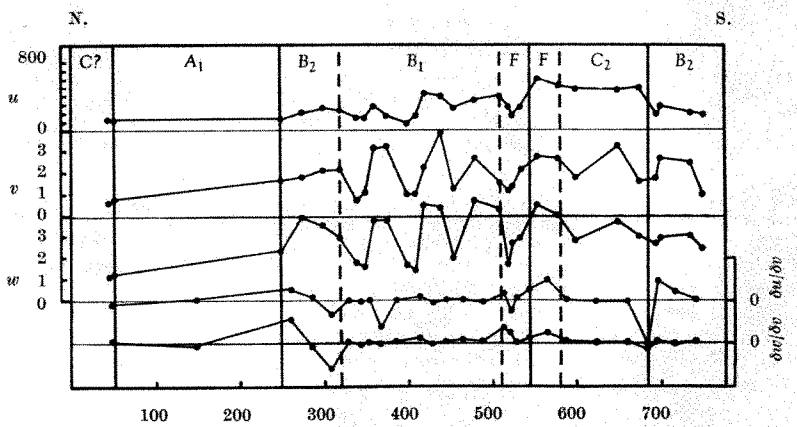

Fig. 3. Graphs of u, v, w, $\delta u/\delta v$ and $\delta w/\delta v$ against distance for Track 3 of the Drake Passage series. The horizontal scale represents distances in nautical miles from Port Stanley; u is measured in gamma, v and w in nautical miles. The vertical dividing lines are divided into two types, solid when obtained from inspection of u, v and w graphs and broken when obtained from inspection of the $\delta u/\delta v$ and $\delta w/\delta v$ graphs

—○—, Division of type; — –○– —, division of degree within one type or type division of uncertain position; ....., tentative correlation of magnetic feature

been possible to define the various type areas described, though, because of the difference in direction of the traverses in the two regions, it is not possible to be sure that any particular type has the same geological significance in both.

Correlation between widely spaced but parallel traverses in the way described presumably depends on the existence of considerable areas which are geologically similar to the extent that the magnetic anomalies produced have certain characteristics in common. If this is correct, the divisions between areas of different magnetic type are likely to be important geological boundaries of which some may be faults. A more detailed analysis of the data than can be described here has suggested that in a large part of the area under discussion the anomalies may be mainly caused by the sub-bottom topography of basic igneous rocks, changes in magnetic type being produced by variations in the form and relief of the topography, which is itself likely to be related to rock type and structure.

Using a seismic profiler it should be possible to show fairly easily whether or not there is any relation between the concealed topography and the magnetic anomalies, and together with detailed seismic refraction surveys the two methods should confirm or disprove the geological significance of the magnetic type boundaries. If the method is found to give geologically useful information it will be worth developing further.

We thank the Director of the British Antarctic Survey for providing facilities for carrying out the field work on which this analysis is based and for the assistance given by his staff. The magnetic measurements were made by P. Kennett and H. A. D. Cameron.

DOSE-EFFECT RELATIONSHIPS FOR RADIATION DAMAGE TO ORGANIZED TISSUES

WHEN a population of cells is exposed to ionizing radiation its ability to give rise to viable daughter cells is impaired, fewer and fewer cells retaining this ability (that is, 'surviving') as the dose is increased. It is well established that the relationship between dose and the survival of mammalian cells is of the pattern illustrated by the curve *OAB* in Fig. 1. This type of survival curve has been observed for cells irradiated and cultured *in vitro* and *in vivo*[1-3]. Although some authors assume that the extrapolation number, N, is usually near 2 for mammalian cells[4], observations made at the cellular level have demonstrated that higher values of N are frequently observed[5-7]. The actual value of N for the cells in a given tissue is of great importance, both for theoretical reasons and for the practice of radiotherapy, and this article summarizes evidence from which it may be deduced that, if cell survival in organized tissues follows the pattern illustrated in Fig. 1, the relevant extrapolation number N may often be very much greater than 2.

The evidence is provided by animal experiments, and by clinical observations, in which a given biological end-point is attained either by a single dose of radiation or by two or more doses separated in time ('fractionated doses'). In general, the total dose when fractionated has to be greater than when given within a few minutes. A rationale for this effect was put forward theoretically[8] on the basis of Gray and Scholes's experiments[9], and was demonstrated experimentally with mammalian cells by Elkind and Sutton[2] from observations *in vitro*. Cells given a dose $\frac{1}{2}D_2$ (Fig. 1) and then allowed to metabolize would reach the survival level *BC* after a further dose $\frac{1}{2}D_2$, whereas if a single dose had been given the same level of survival would have been reached by dose D_1. This is true provided the interval between the fractions is several hours[2]. The difference between D_2 and D_1 is equal to the intercept of *BA* on the 100 per cent survival abscissa, and has been designated D_Q (ref. 10). For two fractions $D_2 - D_1 = D_Q$, and if n equal fractions D_n/n are given, each being large enough to bring the survival to the straight part of the semilog curve in Fig. 1, then $D_n - D_1 = (n - 1)D_Q$. Thus D_Q may be determined by comparing the total fractionated dose with the single dose necessary to give the same effect. It should be pointed out that if the fractions are so small that the cell survival after each dose lies on the shoulder of the curve in Fig. 1, then $D_n - D_1$ will be less than $(n - 1)D_Q$ so that spuriously low values of D_Q would be found by this calculation.

Table 1 shows a number of values of D_Q obtained by observations on mammalian tissues. Pig skin has been found to respond to radiation in a way similar to human skin, and is therefore a useful experimental system[11,12]. The results on human skin were taken from five publications used in a survey of the literature on dose-fractionation[13]. The clinical observations, although less accurate than the results of the experiments on pig skin, are in good agreement with them.

In the experiments in which death of mice within 4 days was studied[14], the lethal effect of radiation was presumed to be due to the lethal effects on epithelial cells lining the crypts of Lieberkühn[15]. We have calculated D_Q for mouse bone-marrow from the data of Brown,

Corp and Mole[16], on the assumption that the death of mice within 30 days is attributable to lethal effects on the stem cells of hæmopoietic tissue[15].

If the dose-effect relationship illustrated by Fig. 1 applies to the test systems cited in Table 1, then $D_Q = D_0 \log_e N$, where N is the extrapolation number and D_0 is the dose required to reduce a surviving fraction f to fe^{-1}, once the survival curve has become exponential. This relation is shown graphically in Fig. 2. D_0 cannot be calculated from the data of Table 1, since the level of cell survival required to give any of the biological end-points is not known. However, an assumed value for either D_0 or N will enable the other unknown constant to be calculated. The available data which establish both D_0 and N for various cell lines have shown a smaller range of values for D_0 (from 84 (ref. 21) to 280 rads (ref. 17)), for well-oxygenated cells, than for N (from 1 to 10 or more).

In Table 1 values for N have been calculated from the data on D_Q for values of D_0 of 100, 150 and 200 rads. It will be seen that all the values of N are greater than 2, some being more than 100. Possible reasons for these high values should be considered.

One possibility is that a fraction of cells in the normal tissues used were anoxic. In this case D_0 is unlikely to be higher than 450 rads, and N for pig skin irradiated in 2 or 3 fractions would still not be less than 4. However, there is no reason to suppose that normal tissues contain significant proportions of anoxic cells. Moreover, there is direct evidence on this point from the experiments on 4-day lethality in mice[14], since those which were irradiated while breathing oxygen were no more radiosensitive than those breathing air.

Another possibility is that systemic factors may play a part when organized tissues are irradiated *in vivo*. These factors might influence cell survival, or might influence the observed response of the animal to a given degree of cellular depopulation. Some support for this hypothesis is given by a comparison of the results of Brown, Corp and Mole[16] on 30-day lethality in mice, with those of Till and McCulloch[18,19], McCulloch and Till[20], and Smith and Vos[21] on the survival of mouse bone-marrow cells. The four latter reports give values of D_0 near to 100 rads with N near to 2, and this cannot be reconciled with the value of D_Q deduced from the data of Brown, Corp and Mole[16]. This value of D_Q between 220 and 270 rads would give N between 9 and 15 if D_0 was 100 rads. On the other hand, the difference may be due to differences between strains of mice. Evidence which supports the relevance of cell survival curves to tissue damage *in vivo* comes from timing studies, which were done in the experiments on pig skin and on 4-day lethality in mice. Elkind and Sutton[2], using split doses on an *in vitro* cell system, found that survival after the second dose varied with time between doses, rising to a maximum, then falling to a minimum, and finally rising to a plateau when the interval was 12 h or more. This pattern has been observed to hold in the two experimental systems quoted. Furthermore, observations *in vitro* have shown that the value of N decreases with increasing linear energy transfer of the radiation, and split dose experiments on 4-day lethality in mice after exposure to fast neutrons have shown that the ratio D_Q/LD_{50} is considerably less than after exposure to X-rays[22]. It seems plausible that the observations are due to events taking place within the cells, and unlikely that unknown systemic factors should operate differently on cells exposed to the different qualities of radiation.

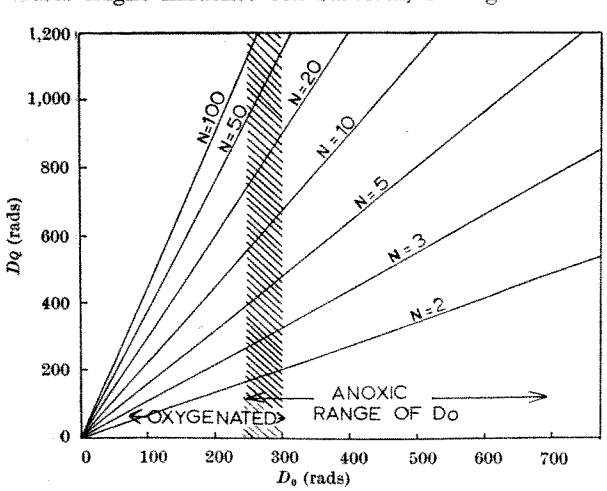

Fig. 2

Cellular re-population could not be a factor in increasing D_Q when the interval between doses was less than a day (the figures quoted in the gut-damage experiments are for an interval of 6 h between doses). In the pig-skin experiments it was found that, for a given degree of skin reaction, irradiation over a total period of 29 days required a dose only 15 per cent larger than that required when the total period was 5 days. The high D_Q values cannot therefore be explained on the grounds of increasing cell populations. Nor can they be explained on immunological grounds, which have been suggested[23] as a factor in explaining the high values of D_Q calculated from fractionation studies on solid tumours, since the experiments discussed here were made on normal tissues.

It is evident, therefore, that some normal tissues behave as though their constituent cells have survival curves with extrapolation numbers much greater than 2, which is sometimes regarded as a 'proper' value for all diploid mammalian cell lines. Although investigation of the possible influence of systemic factors is needed, the figures tabulated in this article have an important bearing on the rationale of dose fractionation in radiotherapy.

Note added in proof. The value of N for bone-marrow calculated from the data of Brown, Corp and Mole[16] was seen to be much higher than that obtained directly[19].

Recently, however, S. Hornsey carried out similar experiments using mice of strain *TO*. Intervals between doses varied from 1 to 24 h. A maximum in the curve of survival versus time between doses was found at 4–6 h, and at this time, as at 24 h, the estimated value of D_Q was about 100 rads. If 100 rads is adopted as the value of D_0 for bone-marrow cells[18–21], this value of D_Q gives $N = 2{\cdot}7$. This good agreement with the value $N = 3$ observed by Till and McCulloch[19] for bone-marrow irradiated *in situ* makes it seem unlikely that the high values of D_Q observed for other tissues are due to systemic effects.

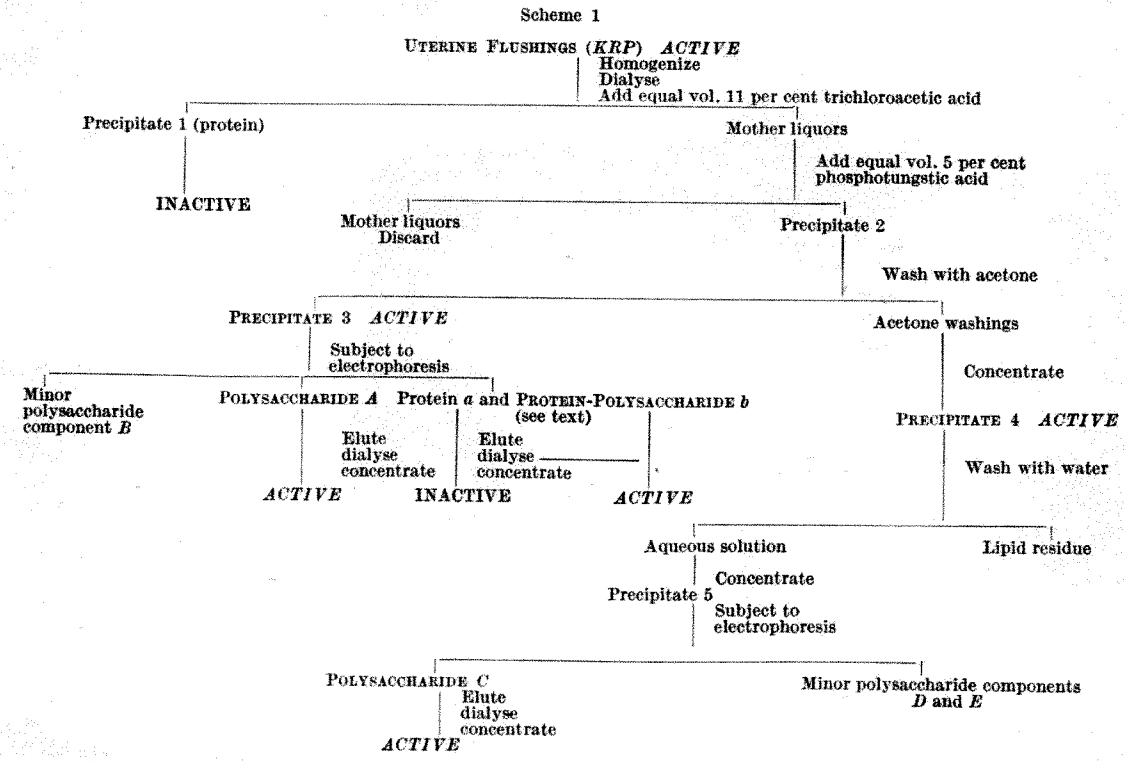
INFLUENCE OF ISOLATED COMPONENTS OF THE UTERINE SECRETION ON PHAGOCYTOSIS

By JEAN KILLINGBECK, Dr. N. B. HAYNES and Dr. G. E. LAMMING

University of Nottingham, Sutton Bonington

In an earlier article[1] it was shown that the uptake of starch particles by polymorphonuclear (PMN) leucocytes was inhibited in the uteri of pseudopregnant rabbits *in vivo* and in the presence of equivalent uterine flushings *in vitro*. No similar suppression of activity was observed with flushings from œstrous rabbits or in the uteri of such animals. It has been suggested that a polysaccharide material, shown to be present in uterine flushings obtained from rabbits during pseudopregnancy, but absent at œstrus, may be responsible for this phenomenon[2].



This article describes the fractionation of secretions obtained from the uterus of pseudopregnant rabbits, and an investigation into the ability of the major fractions of these secretions to inhibit the phagocytosis of starch particles by rabbit PMN leucocytes *in vitro*.

The preparation of experimental animals and collection of uterine secretions were carried out as described previously[1]. Prior to fractionation experiments, a preliminary test was performed to determine whether the activity was due to compounds of a heat-labile nature (the term 'active' is used throughout this article to denote a definite suppression of phagocytic activity relative to a control). No loss occurred on boiling an active secretion for 10 min before incubation with leucocytes and starch granules.

The fractionation procedure, together with activities of various fractions, is shown in Scheme 1.

This procedure was carried out several times, initially on flushings obtained from individual uterine horns and finally on a series of combined flushings from the uteri of five pseudopregnant rabbits. The fractions are designated

Scheme 1

protein, polysaccharide, and lipid by virtue of their staining properties only. The fractionation was carried out at room temperature except where solutions were concentrated (40° C at reduced pressure) and where components were eluted from paper. Precipitates were collected by centrifuging. Fractions were submitted to dialysis where stated, for 72 h, against several changes of distilled water. Electrophoresis was performed on 25-cm strips of Whatman No. 3 paper at 300 V for 3 h in various buffers, the material being applied in the same buffer as that used for the electrophoresis. Precipitate 4 was dissolved in 80 per cent aqueous acetone and applied to paper in order to demonstrate that the lipid fraction remained at the origin during electrophoresis. Preparative electrophoresis was carried out on 25 cm × 15 cm sheets of the paper already mentioned, the material being applied in streaks, detected by edge staining, and the portion of paper containing the required polysaccharide eluted with boiling water. The electrophoretic properties of these components were not affected by short periods in boiling water and a good and rapid recovery was obtained from the paper in this way. Portions of paper containing protein were eluted with water at room temperature. 0·2 M borate buffer, *p*H 7·5, was used throughout for preparative work apart from the separation of protein *a*. Electrophoretic mobilities and the staining properties of the fractions, together with those of heparin in various buffers, are shown in Table 1.

Table 1. Electrophoretic Mobilities and Staining Properties of Fractions from Uterine Flushings

	Electrophoretic mobilities (cm) (all migrating to anode)			Staining reactions		
	0·2 M Acetate *p*H 4·0	0·5 M Borate *p*H 10·1	0·2 M Borate *p*H 7·4	Toluidine blue	Bromophenol blue	Sudan black
Polysaccharide *A*	3·0	12·0	8·0	+ + (blue)	—	—
Polysaccharide *B*	2·0	9·5	—	+ (blue)	—	—
Protein *a*	Origin	5·0	—	—	+ +	—
Protein–polysaccharide *b*	—	—	4·5	+ (blue)	+ +	—
Polysaccharide *C*	8·5	13·5	11·0	+ + + (purple)	—	—
Polysaccharide *D*	3·5	9·0	8·0	+ (purple)	—	—
Polysaccharide *E*	2·0	6·0	6·5	+ (blue)	—	—
Precipitate 4 (lipid residue)	Origin	Origin	Origin	—	—	+ + +
Heparin	7·5	9·0	8·0	+ + + (purple)	—	—
Ppt 1 (protein)	—	—	—	—	+ +	—

After fractionation, activity determinations were carried out on the major polysaccharide and protein fractions from the flushings. The leucocytes were collected and phagocytic activity was measured as described in the previous article[1]. In the determination of activity a quantity of material approximating to that found in a single uterine horn was dissolved in 2 ml. of Krebs–Ringer phosphate solution (KRP). Leucocytes and starch particles suspended in this solution alone were used as a control. Other workers have reported that serum containing complement and antibody is necessary for the uptake of starch particles by guinea pig leucocytes[3,4]. However, in these experiments, although preliminary work showed that the uptake of starch particles increased in the presence of serum, leucocytes continued to show considerable phagocytic activity when no serum was present and this activity did not diminish when the leucocytes were washed with isotonic saline prior to incubation. Thus it was concluded that rabbit leucocytes differ from those obtained from guinea pigs in retaining their ability to engulf starch particles in the absence of serum. Phagocytic activity (per cent) of the leucocytes in the presence of the various fractions is shown in Table 2.

Activity equivalent to that found with the original flushings occurred with precipitate 3 and polysaccharide *A*, whereas precipitate 1 (protein) showed no activity.

Table 2. Phagocytic Activity (per cent) in the Presence of Various Fractions of the Uterine Flushing

	No. of starch particles per leucocyte			
	0	1–10	11–20	> 20
Control (Krebs–Ringer phosphate)	0·4	6·2	28·6	64·8
Untreated flushings	13·4	74·1	9·4	3·1
Precipitate 1	—	12·8	38·2	49·0
Precipitate 3	5·9	69·4	18·9	5·8
Precipitate 4	11·2	60·5	26·5	1·8
Polysaccharide *A*	0·3	60·0	30·3	9·4
Polysaccharide *C*	2·0	53·3	41·3	3·4
Protein *a*	3·0	22·0	40·0	35·0
Protein–polysaccharide *b*	21·0	63·0	15·0	1·0

Precipitate 4 and polysaccharide *C*, while inhibiting uptake of starch particles, also caused agglutination of PMN leucocytes, rendering the counting procedure less accurate in these cases. Protein–polysaccharide *b* obtained from precipitate 3 after electrophoresis in borate buffer *p*H 7·5 showed heavy staining for protein with bromophenol blue, slight polysaccharide staining with toluidine blue, and was active. On the other hand, protein *a* obtained from the same precipitate after electrophoresis in borate buffer *p*H 10·1 showed no polysaccharide staining and was inactive. It was not possible to determine activities of the dialysable material since concentrates caused degeneration of the PMN leucocytes, presumably due to the high inorganic content of these. The lipid residue was insoluble in Krebs–Ringer phosphate and was not investigated further.

These results indicate that the inhibitory effect of uterine flushings from pseudopregnant rabbits on phagocytosis can be repeated after fractionation. The final major components (excluding protein-polysaccharide *b*) which caused suppression of phagocytosis consisted of material staining only for polysaccharide. It is not known whether protein–polysaccharide *b* consists of protein and polysaccharide in chemical combination at *p*H 7·5, or of chemically distinct entities with the same electrophoretic mobility. It is reasonable to suppose, however, in view of the results from other fractions, that the polysaccharide portion of *b* is responsible for its activity. In the case of polysaccharide *C* and precipitate 4 it is possible that the inhibition may have been associated with the agglutination effect. This property does not appear to be a function of concentration since it persists when these fractions are diluted further before determinations of activity. None of the other components produced any noticeable agglutination effects.

The whole surface of the leucocytes, in solutions showing activity, stained heavily with 0·5 per cent toluidine blue. In the control treatment only the nuclei were lightly stained. This suggests that the polysaccharides may produce their effects by adsorption on the surface of the leucocytes. In solutions of the active components in higher concentration, the PMN leucocytes were observed to become more rounded and distinct, which again suggests a surface effect. It is thought that adsorption of a particle on the surface of a leucocyte is the first stage of phagocytosis[5,6]. Thus it seems probable that adsorption of a polysaccharide on the cell surface could interfere with this process and hence prevent the entry of the particle into the cell.

The presence of protein and lipid material at a late stage in the fractionation indicates that the active fractions studied are breakdown products from larger molecules which occur in uterine secretions and which contain protein, lipid and polysaccharide in some form of combination.

We thank Dr. M. J. Wolf, Northern Regional Research Laboratory, U.S. Department of Agriculture, Peoria, Illinois, for a gift of starch from *Amaranthus cruentus*.

MECHANISM OF REJECTION OF HOMOTRANSPLANTED KIDNEYS

By Dr. S. L. KOUNTZ*, M. A. WILLIAMS, Dr. P. L. WILLIAMS, Dr. C. KAPROS† and W. J. DEMPSTER
Department of Surgery, Postgraduate Medical School of London, and Department of Anatomy, Guy's Hospital Medical School of London

RENAL homotransplants in mammals usually cease to function within a few days or weeks[1]. The functional arrest of such kidneys is commonly attributed to immunological causes; but the exact mechanism has not been elucidated. Darmady *et al.*[2] demonstrated the evolution of histological changes within the homotransplanted kidney using stains for nucleic acids. The methyl-green-pyronine stain reveals stages in the evolution of the plasma cell within the homotransplant, similar to those described by Fagraeus[3].

With the notable exception of Dempster[4], workers in the field of transplantation biology have interpreted the plasma cell as a mobile effector of an immune response mounted by the host[5–7]. While it now seems certain that a portion of the pyronine positive cells are of host origin[8–10], little consideration has been given to the means by which these cells could bring about oliguria and disintegration of the homotransplanted kidney.

The work recorded here was designed to investigate the pathophysiological and anatomical changes within the homotransplanted kidney. Evidence will be presented to show that the destruction of renal homotransplants is an ischæmic process. This is brought about by progressive dissolution of small blood vessels by immature plasma cells, followed by the blockage of the intertubular spaces by plasma cells, red cells, leucocytes and rounded, isolated endothelial cells.

The experiments were performed on greyhound bitches with an average weight of 22–25 kg. In the first series of experiments a right nephrectomy was performed followed by auto- or homo-transplantation to the right iliac fossa. The technique was that described by Dempster[11], in which the renal artery was anastomosed end-to-side with the external iliac artery, and the renal vein end-to-end with the external iliac vein; and the ureter implanted into the bladder. Renal venous flow was determined prior to transplantation and during the life-history of the homotransplant, using a constant local indicator dilution method[12,13]. During placement of the catheters in the renal veins for measurements of venous flow, successive wedge biopsies of the cortex were taken. Small cubes from the centre of the biopsies were preserved in Palade's buffered osmium fixative for electron microscopy, and other portions fixed for light microscopy. Oliguria in the homotransplant was considered imminent when a significant fall in the serum antitrypsin-level occurred[14].

In a second series of experiments, the 'effective renal blood flow' and simultaneous '1 h percentage excretion' in the urine following a single intravenous dose of 20 μc. iodine-131-hippuran and 4 μc. of carbon-14-inulin were estimated daily on bilaterally nephrectomized, unanæsthetized dogs bearing an auto- or homo-transplanted kidney. Effective renal blood flow was measured by the rate of disappearance of the single intravenous dose of iodine-131-hippuran[15,16]. Iodine-131 and carbon-14 were assayed simultaneously in a Packard 'Tri-Carb' liquid scintillation counter, model 314 *EX*, using a gel scintillator. Oliguria of a homotransplant was taken to be the point when a sudden decrease in the daily urine volume and a poor response to an infusion of 500 ml. of 0·9 per cent saline and 300 ml. of 2 per cent saline occurred[17].

The variable survival times of renal homotransplants in dogs necessitates frequent observations on individual transplants. Single observations have little value. Renal venous flow was measured during the survival of 34 renal homotransplants and six autotransplants. The results of a typical homotransplant experiment are shown in Fig. 1. The usual period of ischæmia which is involved

Calculated percentage of injected dose remaining after 1 h	58·8	—	63·0	56·6	35·6	36·5	29·6
Measured percentage excreted in urine in 1 h	35·4	—	35·4	43·3	61·0	64·2	62·4
Total	94·2	—	98·4	99·9	96·6	100·7	92·0

during transfer results in a post-transplantation decrease in flow, which returns to normal or near normal within 24 h. After 24–72 h there is a progressive decrease in venous flow until oliguria, after which it rapidly ceases. Except for the post-transplantation decrease in flow, venous flow was maintained at virtually normal levels in autotransplants.

In Fig. 2 a typical experiment shows the changes in the daily effective renal blood flow and the daily simultaneous 1 h percentage excretion in the urine of a single dose of 20 μc. of iodine-131-hippuran and 4 μc. of carbon-14-inulin by a homotransplanted kidney. The ischæmia during transfer again results in a post-transplantation decrease in flow, which returns to normal or near normal within 24 h. This was followed within 72 h by a progressive fall until oliguria. The percentage recovery of the 20 μc. of iodine-131-hippuran injected intravenously was determined by adding the amount measured in the urine to the calculated amount remaining in the animal after 1 h. The percentage of the dose remaining after 1 h was calculated by the following formula:

$$\frac{^{131}\text{I in 1 ml. plasma at 1 h} \times 100}{^{131}\text{I in dose}} \times V$$

where V is the thereotical volume of distribution. In Table 1 the results of the dog illustrated in Fig. 2 are shown. The 1-h percentage excretion in the urine of the injected dose also fell progressively after 24–72 h until oliguria, but not so rapidly as the effective renal blood flow.

The results of electron microscopy are summarized in Table 2. Although minor tubular changes are seen before oliguria, they are not progressive or serious in extent. No glomerular changes were observed (Fig. 3). In contrast to the foregoing, extensive and progressive vascular damage appeared as a major lesion. Oliguria occurred when the flow of blood was greatly reduced by blocked (Fig. 6) and damaged blood vessels. At this point tubular necrosis commences.

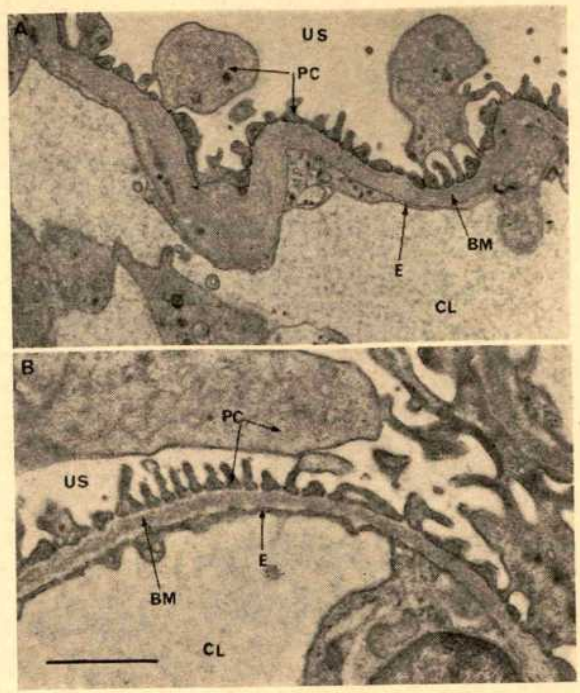

Fig. 3. *A*, Morphologically normal glomerular tuft in an anuric homotransplant of kidney; *US*, urinary space; *PC*, podocyte cytoplasm; *BM*, basement membrane; *E*, endothelium; *CL*, capillary lumen. *B*, Morphologically normal glomerular tuft in a functioning autotransplant. Labels as for *A*. Scale = 2μ

Table 2. Summary of Electron Microscopic Findings

Type and No. of specimens	Glomeruli	Proximal convoluted tubule	Distal convoluted tubule	Intertubular vasculature
Autotransplants (5)	Endothelium, basement membrane and podocytes normal.	Slight luminal shedding of cytoplasm, microvilli and free mitochondria. Slight increase in basal vacuolation.	Normal. Debris in lumen from proximal tubule.	Normal.
Functioning homotransplants (*a*) 24 h (2)	Normal, but contains refluxed mitochondria in urinary space.	Large numbers of small basal vacuoles. Luminal shedding more intense than in autotransplants.	Normal. Debris in lumen as above.	Erythrocyte sludging in a few vessels.
(*b*) 72 h (2)	Normal.	Marked luminal cytoplasmic shedding. Intertubular œdema. Many small basal vacuoles present.	Normal. Debris in lumen. Intertubular œdema.	Numerous intravascular and extravascular lymphocytes, immature and maturing plasma cells. Intimate cell membrane apposition of plasma cells and endothelial cells (Fig. 4)—patchy disappearance of intervening membranes with cytoplasmic continuity (Fig. 5). Endothelial cells separate from each other, round up and extrude cytoplasmic blebs.
(*c*) 96 h (1)	Normal.	As for 72 h.	Normal. Debris in lumen. Intertubular œdema.	Extravascular red cells, lymphocytes, plasma cells. Free mitochondria in lumen of vessels remaining intact. Many isolated masses of endothelial cytoplasm. Numerous rounded endothelial cells, some remaining in close apposition with plasma cells. Increase in intertubular collagen.
(*d*) 9 days (1)	Normal.	As for 72 h.	Normal.	Vessel area chaotic. Many free rounded endothelial cells, fewer plasma cells, much cytoplasmic debris and free red cells. Scattered masses of intertubular collagen.
Oliguric homotransplants (6)	Normal.	Shedding still occurring but large basal vacuoles present.	Normal. Debris in lumen.	Majority of intertubular vessels destroyed or blocked (Fig. 6). Intertubular spaces filled with red cells, rounded endothelial cells, collagen, and isolated plasma cells and phagocytes.
Anuric homotransplants (1)	Normal (Fig. 3).	Much cytoplasmic shedding. Large basal vacuoles in various stages of coalescence. Some tubules completely necrotic.	Most tubules normal. Some show early basal vacuolation.	Vasculature obliterated. Interstitium full of red cells, many active phagocytes and much scattered collagen (Fig. 7).

L, lymphocyte; *PC*, immature plasma cell; *EC*, endothelial cell; *BM*, basement membrane of neighbouring proximal tubule. Scale = 2μ

Measurements, by other workers, of blood flow in transplanted kidneys have been limited in the main to single observations[2,18,19]. Such observations did not permit a full assessment of the hæmodynamic changes occurring within the homotransplant. The observations reported here permit the formation of a theory for the rejection of first set renal homotransplants.

They indicate that the destruction of first set renal homotransplants is an immunological reaction mediated by host cells arriving via the blood stream. These cells are in the main immature plasma cells and appear to be directed specifically against the intertubular blood vessels. Following homotransplantation the resulting lesion becomes visible within 24–72 h. The initial point of attack is the vascular endothelium of the small intertubular vessels. Plasma cells enter into close cell membrane apposition with the endothelial cells over quite wide areas (Fig. 5). For the most part, a featureless 200 Å gap persists between the cells, but at scattered points there is a temporary dissolution of the adjacent membranes with the establishment of cytoplasmic continuity between the cells. In addition, scattered along the adjacent membranes, in a nodose fashion, are patches of increased density (about 0·1μ in length). This increased osmiophilia involves both the unit membranes themselves and also elliptical areas of the adjacent cytoplasm of the endothelial and plasma cell. The points of cytoplasmic continuity and of increased density may well be the sites of cytoplasmic interchange of materials between the cells. In this connexion it is interesting to note an apparent increase in the complement of free ribosome rosettes in endothelial cell cytoplasm at this stage.

During the apposition phase the attenuated outlying parts of the endothelial cells partially withdraw towards the nucleus and in part round up and become extruded as free, ribosome studded, anucleate masses.

The separation of adjacent endothelial cells results in the extravascular escape of red cells, and this is accompanied by a further accumulation of both intra- and extravascular plasma cells and lymphocytes. Concomitant with the vascular damage is a progressive decrease in total blood flow. The daily 1-h excretion of a single intravenous dose of inulin and hippuran reflect to a much smaller degree the vascular damage during the period of adequate function. The progressive attack on the smaller blood vessels by immature plasma cells culminates in: (1) the separation, rounding-up and final isolation of the endothelial cells; (2) the accumulation of plasma cells, lymphocytes, red cells, cell debris and ultimately phagocytes in the areas previously occupied by intertubular vessels (Fig. 7). The progressive damage to, and disappearance of intertubular vessels, the intertubular œdema and the massive interstitial cellular accumulation, together result in the total renal blood flow being severely reduced so that tubular perfusion becomes inadequate. At this point oliguria is initiated and tubular necrosis commences with massive vacuolation of the cells of the proximal convoluted tubules. Oliguria proceeds rapidly to anuria with physical destruction of larger blood vessels and hæmorrhage.

Although some shedding of proximal convoluted tubular cytoplasm occurs throughout the life history of renal homotransplants, it is not progressive in nature; while final tubular necrosis appears to be secondary to the primary immunological attack on the blood vessels. No evidence has been produced for an immunological attack on renal parenchymal cells.

The plasma cell attack is well under way by the fourth day and is probably initiated within 48 h after homotransplantation. While this is occurring, the host is apparently unable to mount a second set response[20]. One explanation may be that antigen is released in minute quantities only, which is insufficient to sensitize systemically the host, or alternatively antigen is a fixed surface component of the endothelial cell and stimulates the effector cell only during direct contact. The rapid response is probably effected by certain undefined but immunologically competent cells already circulating in the blood stream at the time of transplantation.

Vascular destruction has been incriminated as the cause of rejection of rat skin homografts but the effector cell would appear to be different[21].

EFFECTS OF PLANT GROWTH REGULATORS (AUXINS AND AUXIN ESTERS) ON THE SURVIVAL OF FREE CELLS OF THE EHRLICH ASCITES CARCINOMA

By Dr. R. D. SCHULTZ
Space Sciences Laboratory
AND
Dr. D. NORMAN
Life Sciences Department, North American Aviation, Inc., Space and Information Systems Division, Downey, California

RECENTLY[1] we reported a lethal effect of indolyl-3-acetic acid ethyl ester (IAEt)* and a protective effect of the natural plant growth regulator, indolyl-3-acetic acid (IAA), on the free cells of a diluted Ehrlich ascites carcinoma[1]. In this article, analogous effects for naphthyl-1-acetic acid methyl ester (NAMe) and for the synthetic auxin, naphthyl-1-acetic acid (NAA), are reported. Also reported is an unexpected effect resulting from the combined action of IAEt and IAA in suspension. This action is more lethal to the carcinoma cells than the action with IAEt alone. In view of the protective action of IAA when used alone, this result is surprising.

We now have evidence, obtained by paper chromatography, that the undiluted ascites tumour destroys IAEt rapidly both *in vitro* and *in vivo*. Such degradation within the tumour cells or in the ascitic fluid is an important factor which could limit or nullify the possible chemotherapeutic applications of auxin esters. For this reason we have been altering the chemical structure of these compounds in order to decrease their rate of degradation and, also, to determine specific structural requirements for optimum cytocidal activity. Some of the compounds have been tested against diluted ascites tumours ; the resultant data are reported here. Related results, obtained with undiluted tumours, will be reported in another communication.

As in our previous experiments[1], free ascites tumour cells were collected from male Webster white Swiss mice (initial body-weight 18–22 g) at 6–10 days post-transplantation by draining the ascitic fluid from the abdominal cavity. On the average, the fluid contained about 3×10^8 cells/ml. In the experiments recorded here, the ascitic fluids from a number of different animals were pooled and diluted by a factor of twenty with the Krebs–Ringer phosphate solution, *p*H 7·15. The final mixture contained glucose at 1 mg/ml., and the relatively insoluble auxins and/or esters (each at 0·5 or 2 mg/ml.) suspended with gum arabic at 1 mg/ml. Controls were

* We are now using the more descriptive symbol IAEt to represent the ethyl ester of indolyl-3-acetic acid, instead of the IAAEE symbol in our previous article (ref. 1).

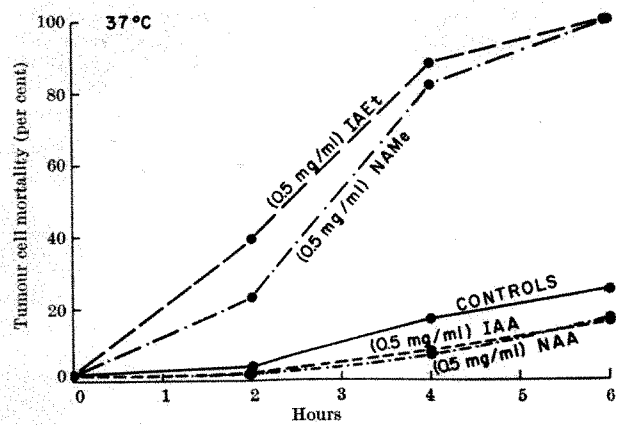

Fig. 1. Lethal effect of suspensions of ethyl indolyl-3-acetate (IAEt), or methyl naphthyl-1-acetate (NAMe), on the survival of free cells of a diluted Ehrlich ascites carcinoma, *in vitro*, at 37° C. Note, in contrast, the protective effect of indolyl-3-acetic acid (IAA), and naphthyl-1-acetic acid (NAA), under similar conditions

prepared in an identical manner, except for the omission of auxins and auxin esters. Incubation at 37° C and cell counting of samples withdrawn at various intervals were performed as described previously[1].

The Krebs–Ringer–glucose solution is a medium designed for short-term studies with isolated, live, animal tissues. The medium cannot support the life of the tumour cells indefinitely. After a 4-h incubation at 37° C, significant cell mortality could be observed in controls of some tumour preparations (Fig. 1); in other preparations, little mortality was observed even after 6 h. However, a 0·5 mg/ml. suspension of IAA or of NAA appreciably reduced the rate of cell mortality of a sensitive tumour preparation. In contrast, the corresponding esters, IAEt and NAMe, killed 39 and 23 per cent, respectively, of such tumour cells in 2 h, compared with less than a 4 per cent death in the untreated controls. After 6 h, these auxin esters had killed 100 per cent of the cells, compared with about a 25 per cent mortality of the controls, and only a 17 per cent death of those cells treated with the free auxins.

The difference between the effects of auxin esters and auxins on the tumour cells is evident. We attempted to use this difference to influence the kinetics of possible enzymatic processes related to the cytocidal action of the auxin ester. Accordingly, the tumour cells were exposed to a suspension of IAA (0·5 mg/ml.) plus IAEt (0·5 mg/ml.). In this way it was discovered that the auxin in conjunction with the auxin ester increased the rate of kill (Fig. 2). This result was unexpected because, as has been seen, auxin, when used alone, prolonged the life of the tumour cells. A similar test, with the ratio of IAA to IAEt increased to 4 to 1, conclusively demonstrated the decisive part that auxin plays in potentiating the cytocidal action of the auxin ester (Fig. 3). At the end of a 1-h incubation at 37° C, the mortality for the tumour cells treated with the auxin or auxin ester, separately, was 3·4 per cent or 7·3 per cent, respectively; in the same time the two agents together effected a 90 per cent kill.

Some recent results, obtained from paper chromatography, indicate that the natural auxin, IAA, inhibits the rate of degradation of its ethyl ester, IAEt, by the Ehrlich ascites tumour. This observation could be part of the explanation for the aforementioned potentiation of the cytocidal activity of IAEt by IAA.

The cytocidal activity of the ester of indolyl-3-acetic acid against the diluted Ehrlich ascites carcinoma, *in vitro*, is appreciably influenced by the structure of the alkyl group. From Table 1 it can be seen that the normal or tertiary butyl ester of IAA showed a rate of kill four times greater than the rate of IAEt. The normal pentyl ester killed only about twice as rapidly as IAEt. Surprisingly, however, the methyl, normal propyl and iso-

Table 1. Cytocidal Activity of Various Esters of Indolyl-3-acetic Acid against a Diluted Ehrlich Ascites Carcinoma

IAA ester	Concentration (mg/ml.)	Cell mortality after incubation at 37° C (%) (0 h)	(1 h)	(2 h)	(4 h)
Control	0·0	2·0	2·2	2·1	2·4
IAMe*	0·5		5·2	5·2	11·1
IAEt	0·5		6·4	41·5	91·6
IAPr(n)	0·5		2·5	8·0	7·9
IAPr(i)	0·5		1·1	2·6	2·8
IABu(n)	0·5		99·7		
IABu(t)	0·5		100·0		
IAPe(n)	0·5		21·7	83·9	100·0

* Me, methyl; Et, ethyl; Pr(n), normal propyl; Pr(i), isopropyl; Bu(n), normal butyl; Bu(t), tertiary butyl; Pe(n), normal pentyl.

propyl esters were markedly inferior in cytocidal activity to IAEt. Thus, these data indicate that there is no simple correlation of cytocidal activity with the size of the alkyl group. Also, the data do emphasize the advantages of rapid, inexpensive, *in vitro* screening procedures prior to detailed studies of the carcinolytic activity of auxin derivatives *in vivo**.

We share the opinion of Apffel, Tregier and Homburger[2] that synthetic plant growth regulators, particularly auxin esters, are a new family of compounds that deserve intensive study to determine the nature of their biochemical interaction with animal neoplasms. It is important to keep in mind that some of these compounds are closely related to selective herbicides, used commercially as weed killers, such as the synthetic auxin, 2,4-dichlorophenoxyacetic acid (2,4-D). Audus[3] notes that plant roots are so sensitive to auxins that their growth can be stopped by the extremely small concentrations of natural auxins which normally occur in the shoot. However, for synthetic auxins to be effective as herbicides, considerably greater concentrations must be supplied. For example, a 2,4-D solution, 1 part in 100 million, will inhibit the growth of the seedling root of a susceptible plant such as garden

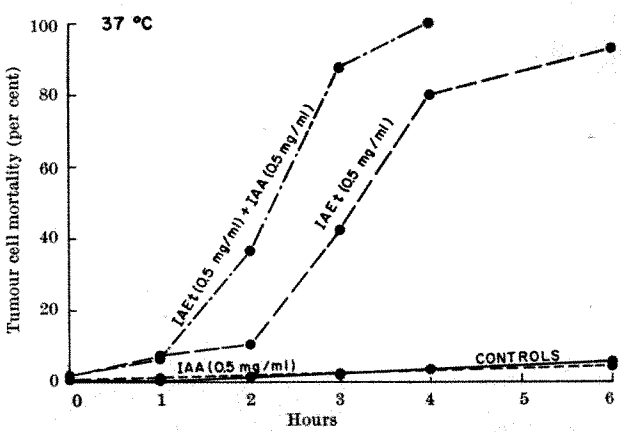

Fig. 2. Potentiation by IAA of the cytocidal activity of IAEt against a diluted Ehrlich ascites carcinoma, *in vitro*, at 37° C

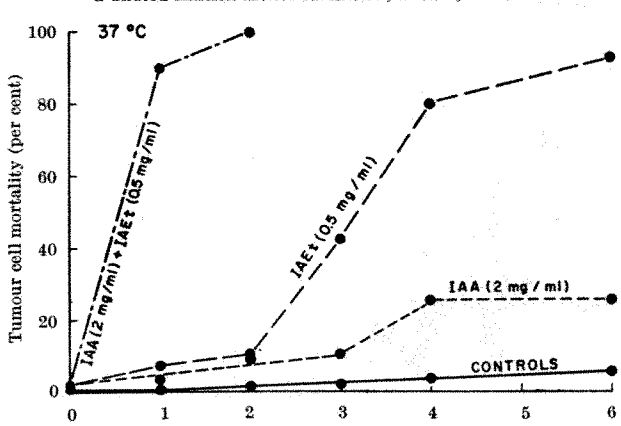

Fig. 3. Synergistic cytocidal activity of IAA plus IAEt, in a 4 : 1 ratio, against a diluted Ehrlich ascites carcinoma, *in vitro*, at 37° C. Note that, by itself, the higher dose of IAA in this test has a weak cytocidal action, instead of a protective action

cress. However, the concentration must be increased to 1 part in a million to stop all root growth and partially to inhibit germination. A leaf spray with a concentration of 100 p.p.m. or even 1 part per thousand must be used to kill the mature plant. It is the opinion of Audus[3] that, at such concentrations, one is no longer dealing with the normal physiological inhibition by the auxin. Instead, one has entered into a concentration region in which the auxin is acting as a cell poison. The growth processes, in which the natural auxin normally plays a fundamental part, are presumably clogged by a vast excess of the synthetic auxin and "a completely chaotic jumbling of the delicately interwoven pattern of normal growth processes is the result"[3].

Conceivably a synthetic auxin could be developed which would 'clog' the growth processes of an animal tumour cell without harming normal cells, somewhat in the manner that a selective herbicide kills weeds in a lawn of healthy grass. Of interest, therefore, is the report of Apffel *et al.*[2] that methyl esters of certain synthetic auxins inhibited the growth-rate of transplanted adenocarcinoma *H2717J*, and of spontaneous breast adenocarcinoma, in mice; this inhibition occurred at dose levels appreciably under the LD_{50}. However, under similar test conditions these particular esters showed little or no carcinostatic activity against the Ehrlich ascites carcinoma[2]. However, as noted earlier in this article, a lack of such activity might in some cases be due to the degradation of the auxin ester by the tumour.

We thank Dr. E. R. van Driest and Dr. Toby Freedman for their encouragement. We also thank M. M. Blair, F. J. Compton, Dr. J. Finn, Dr. S. Johnson, J. Krasner, Dr. M. D. Schwartz, J. G. Wells and H. A. Storms of the Space and Information Systems Division, North American Aviation, Inc., for their assistance in obtaining financial support.

**Note added in proof.* Tests, at present in progress, indicate that daily intraperitoneal injections of IAPe(n) (the normal pentyl ester of IAA), 10 mg total, suspended in physiological saline, will triple the survival time of male Webster white Swiss mice bearing the Ehrlich ascites carcinoma. Treatment was started 1 day post-transplantation. Of special significance is the fact that normal healthy mice given similar daily injections of IAPe(n) have shown no gross evidence of acute or cumulative drug toxicity.

KININ-INDUCED DIRECTED TRANSPORT AND SENESCENCE IN DETACHED OAT LEAVES

By Dr. B. E. S. GUNNING and W. K. BARKLEY
Department of Botany, The Queen's University of Belfast

KINETIN (6-furfurylaminopurine) is known to delay senescence in detached leaves of certain plant species[1-3]. Möthes *et al.* have associated this with another response to kinetin, namely, the accumulation and retention of metabolites in treated areas of leaves, which they have called "kinetin-induced directed transport".[2] The experiments summarized here are concerned with the way in which oat-leaf blades react to kinetin, and illustrate how the responses vary in leaves and leaf tissues of different ages.

The detached blades we have used are terminal 6-cm portions cut from first leaves of *Avena sativa* (var. Victory) seedlings grown under fluorescent lamps. These blades are convenient for 'floating' and 'drop' treatments. In the former, they are floated adaxial side up on test solutions, and in the latter, 0·01-ml. drops are placed on the adaxial surface. In all cases, the blades were kept in a water-saturated atmosphere in darkness during the period of treatment.

In experiments involving movement of labelled materials, the distribution of radioactivity in the blades was ascertained by passing them individually through a chromatogram scanner. Although it is possible to scan living blades repeatedly and thus follow movement during the course of treatment, we have generally dried the blades before scanning. This reduces self-absorption, and, in our conditions, does not bring about longitudinal movement of radioactive material in the blade tissues.

Fig. 1 shows some typical traces of the distribution of carbon-14 and phosphorus-32 in blades passed into the scanner at 6 in./h. A $\frac{1}{16}$ in. collimator slit under the detector provided sufficient resolution, and a twice magnified trace was obtained on a chart recorder running at 12 in./h. As indicated in Fig. 1, radioactive substrates were supplied to the tips of the blades, while the bases received 0·01-ml. drops containing 0·3 μg kinetin. Traces (*a*) to (*d*) illustrate accumulation of labelled material at the kinetin-treated area after 1, 2, 3, and 4 days, when the source at the tip of each blade was a 0·01-ml. drop containing 0·1 μc. glycine-2^{14}C. Dashed traces represent controls without kinetin. Traces (*e*) and (*g*) are controls for two other sources—a photosynthetically labelled tip region, and a 0·1 μc. drop of phosphate solution labelled with phosphorus-32 respectively. Traces (*f*) and (*h*) represent the corresponding kinetin-treated blades, which were dried (with the controls) 40 h after the commencement of the experiment.

With all three sources it is clear that radioactivity accumulates in the tissues under or close to the kinetin drop. In other experiments this effect has been measurable after as short a period as 12 h, and more sensitive methods would doubtless detect it earlier. The lowest active dose for kinetin 'drop' treatments is 0·001–0·003 μg. 6-Benzylaminopurine is as active as kinetin, while the 6-phenyl analogue is less active. Gibberellic acid, indolyl-3-acetic acid, benzimidazole, diphenylurea, and a selection of purines and pyrimidines and their anti-metabolites have not shown comparable activity. No movement occurs in a nitrogen atmosphere.

To obtain these traces, the scanner was adjusted to a sensitivity suitable for measuring radioactivity at the kinetin-treated part of the blades. In the case of glycine-2^{14}C this was less than 10 per cent of the total absorbed by the tip, so that (as with labelled phosphate) the trace went off-scale as the tip approached the collimator-slit. Much of this residual activity is extractable with 70 per cent ethanol, but it is also present in ethanol-insoluble molecules. Thus, stripping-film autoradiography using Kodak '*A.R.*10' emulsion shows heavy labelling in guard-cells and all underlying tissues near the glycine-2^{14}C drop. On the other hand, photosynthetic labelling (by illuminating blade-tips in an atmosphere containing $^{14}CO_2$) evidently provides labelled molecules in a much more available form, for in this case the 'kinetin' and 'tip' peaks on the traces are comparable in size. Movement is almost certainly through the vascular tissues, since in stripping-film autoradiograms of sections cut from the central region of blades provided with glycine-2^{14}C at the

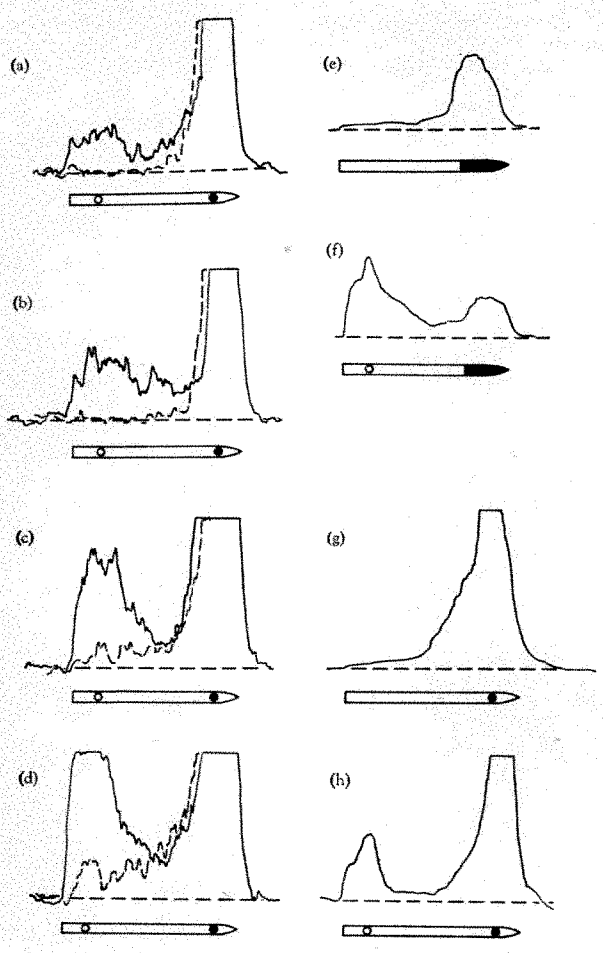

Fig. 1. Distribution of radioactivity in detached oat-leaf blades following application of labelled substrates to the tips (black circles and tips), and kinetin to the bases (open circles). In (*a*)–(*d*) dashed traces represent controls without kinetin. Horizontal lines show the level of background radioactivity

tips and kinetin at the bases, these are the only tissues that contain radioactive, ethanol-insoluble material. At the kinetin-treated area, however, labelling is general, indicating that all tissues receive transported molecules.

As in other species[3,4], carbon-14 becomes incorporated into protein and nucleic acid in kinetin-treated areas of oat leaves. Results of experiments in which such areas have been fractionated by grinding and differential centrifugation (largely according to the methods of Smillie[5]) indicate that the ribosomes play a key part in this aspect of kinetin action. The fractionation procedure we have used provides pellets of particles sedimenting over the ranges: 0–1,500*g*, 1,500–15,000*g* and 15,000–75,000*g*. The two low-speed fractions are washed and re-centrifuged before analysis, and the high speed (90 min centrifugation) pellet is analysed directly. Protein and nucleic acid are removed from the final supernatant by addition of 5 per cent trichloroacetic acid at 1° C.

Fig. 2 illustrates the time course of entry of carbon-14 from transported glycine-2^{14}C into these fractions. Fig. 1(*a*), (*b*), and (*c*) correspond to the 1-, 2-, and 3-day stages given in Fig. 2. Only the basal, that is, the kinetin-affected parts of the blades were fractionated.

Kinetin increases the radioactivity (Fig. 2(*a*)) and the nitrogen-content (Fig. 2(*b*)) of all fractions. The latter effect is not marked in the case of the 15,000–75,000*g* particles, but by contrast they do become highly labelled. This is best seen in Fig. 2(*c*), where changes in a form of specific activity, namely, radioactivity per unit nitrogen, are plotted. After one day of kinetin-influenced metabolism their 'specific activity' is more than twice that of any other fraction. Preferential labelling is maintained, although afterwards the soluble fraction does show higher values.

Similar results are obtained if labelled phosphate or $^{14}CO_2$ photosynthates are used as sources of label. In both cases, only the soluble fraction exceeds the 15,000–75,000*g* pellet in 'specific activity' after two days of kinetin treatment. Since phosphorus-32 and carbon-14 both enter these particles, it follows that their intense labelling is not simply a consequence of radioactive proteins forming on them. Electron microscopy of these mesophyll cells shows that the cytoplasmic ground-sub-

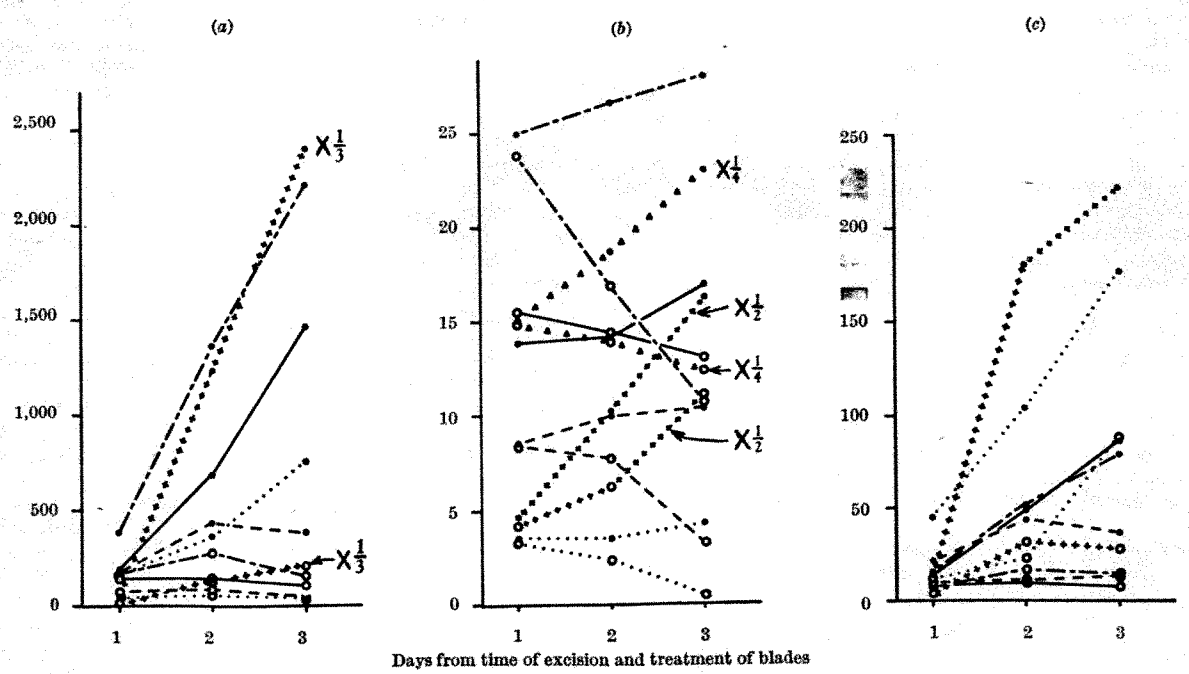

Fig. 2. (*a*) Counts per min, (*b*) μg nitrogen, (*c*) counts per min per μg nitrogen, in 2-cm basal portions of blades treated with glycine-2^{14}C at the tips and with (solid circles) or without (open circles) kinetin at the bases. Each sample, taken daily from the start of the experiment, consisted of 50 bases, and results are expressed per single base. Fractions: ——, 0–1,500*g*; – – –, 1,500–15,000*g*; ....., 15,000–75,000*g*; —·—·—, trichloroacetic acid-insoluble fraction from supernatant; + + + +, final 'soluble' fraction from supernatant; ▲▲▲, total nitrogen

stance and the chloroplast stroma are rich in ribosome-like particles (Gunning, in preparation). Assuming that protein synthesis in leaf cells occurs on such particles, and that they constitute a large part of the high-speed pellet, it seems likely that transported label becomes incorporated into their ribonucleoprotein as well as into protein that is afterwards freed. It is not yet known at what stage on the chain of events leading to protein synthesis kinetin is active, but the rapid entry of phosphorus-32 into ribosomes might suggest a primary effect on nucleic acid metabolism.

Additional evidence comes from experiments in which blade-bases are infiltrated with ribonuclease prior to treatment with kinetin. As compared with controls infiltrated with water, such bases receive much less nitrogen from the more apical regions. Glycine-2^{14}C transport is inhibited, and soluble (amino, acid, and neutral), protein, and nucleic acid fractions all show reduced labelling, as do all pellets and fractions obtained in the cell-fractionation mode of analysis.

The primary effect of kinetin could be to attract substrates; these could then enter metabolic pathways. Alternatively, kinetin could create a metabolic 'sink', with consequent attraction and utilization of substrates. In the first case, if ribonuclease were to inhibit ribonucleic acid-mediated pathways, it might be expected that transported soluble compounds would accumulate. This does not occur. In the second case, utilization of substrates, and hence the total amount transported, would be reduced. The results agree more with this interpretation; however, it is still possible that kinetin is active as a nucleic acid macromolecule[6], in which case the ribonuclease might inhibit by preventing formation of the active form. In this connexion it is of interest that ribonuclease preparations (L. Light and Co., "chromatographically purified, protease-free") have some directed transport effect on their own.

The foregoing results all refer to the behaviour of blades cut from 7–9-day-old seedlings. Such blades senesce basipetally, the basal tissues being the most recently formed, and the apical tissues the oldest. Evidence will now be summarized that shows that the effects of kinetin vary according to the stage of development of the treated tissue, and that metabolism is affected even though directed transport may not occur:

(*a*) *Directed transport.* When blades treated with kinetin at the tips and glycine-2^{14}C at the bases are scanned, no directed transport can be detected. Some acropetal movement does occur if the glycine-2^{14}C is placed in the central part of the blade, that is, closer to the kinetin.

(*b*) *Net movement of nitrogen.* There is only a slight inflow of nitrogen into the apical 2 cm of the blades in response to apical applications of kinetin. The scanning results (above) suggest that it is derived from the neighbouring tissue. Nevertheless, nitrogen metabolism at the tip is affected in that just as in bases, 'insoluble' nitrogen levels are maintained, even though the net inflow is less.

(*c*) *Age of leaf.* It is suggested that oat leaf tissue passes through a stage when it is capable of reacting to kinetin by exhibiting directed transport: thereafter, this property is lost. Fig. 3 compares the effects of apical and basal 'drop' treatments of kinetin in blades cut from 5-, 7-, 10-, and 12-day-old seedlings. None of the tip tissues reacts strongly. That this is due to the physiologically advanced age of the tissue is indicated by the fact that even the bases become less active as they age.

(*d*) *Respiration.* The respiratory drift of isolated bases (2 cm long), but not isolated tips, is influenced by kinetin. In these bases, kinetin prolongs a period of low, steady output of carbon dioxide by about three days. This occurs after an initial period of rapid respiration lasting for 12 h from the time of excision of the bases. The effect is another difference between tips and bases, and, in these isolated portions of leaf, it must be independent of the directed transport system.

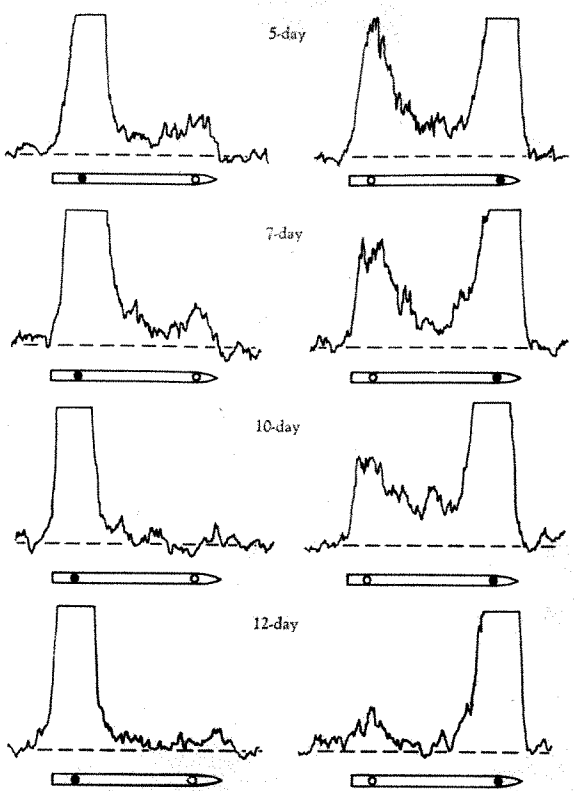

Fig. 3. Acropetal and basipetal transport in blades from 5-, 7-, 10- and 12-day-old seedlings. Open circles, kinetin (0·3 μg); solid circles, glycine-2^{14}C (0·1 μc.). No movement occurred in any minus-kinetin controls

(*e*) *Chloroplasts.* In contrast to the foregoing phenomena, kinetin affects the chloroplasts of both apical and basal parts of blades, and of different ages of leaves. Chlorophyll-levels (as determined by colorimetry of crude extracts) are maintained in treated tissues, while controls turn yellow. In 'floating' treatments, the threshold concentration is between 0·01 and 0·001 mg kinetin/l. 'Drop' treatments have been found to be effective at doses of as little as 0·0001 μg/0·01 ml. Maintenance of pigmentation reflects a general maintenance of chloroplast function, as infra-red gas analysis measurements show that so long as the pigment is present, carbon dioxide is fixed if the leaves are illuminated. The photosynthetic life of bases is prolonged by approximately the same length of time as is the period of low respiration rate.

In summary, kinetin postpones senescence in detached oat leaves. The younger the treated tissue, the more extreme are the effects. In comparatively mature apical regions of leaves, breakdown of chloroplasts is delayed, and 'insoluble' nitrogen-levels are maintained for some time. There is only a slight net gain of substrate from the neighbouring regions of the leaf. In younger tissues, such as are found closer to the basal meristem of the leaf, kinetin induces directed transport in addition to the foregoing effects. The inflowing substrate enters metabolic pathways leading to protein and nucleic acid synthesis, and small particles, probably ribosomes, are preferred receptors of carbon and phosphate derived from older parts of the leaf. Respiratory losses of carbon are reduced. As basal tissues age, they begin to react in the same way as tips, in at least some respects. Conversely, it is possible that leaf apices would show more of the responses demonstrated in bases if they were to be examined at a sufficiently early stage of development.

Since the responses described here occur in darkness, and since kinetin does not increase the respiration rate, the question of the energy source for the various reactions arises. If protein (and other) breakdown processes require

energy in leaf cells as they do in other tissues[7], and if kinetin prevents such breakdown, then the energy that would otherwise have been consumed in this way might become available to drive syntheses. It is not known whether kinetin induces syntheses directly, for example, by stimulating production of ribosomes, or indirectly, as by diverting energy from certain pathways into others. Again, it is not yet known whether the metabolic pathways stimulated under the influence of kinetin are similar to those found in normal cells, or whether certain pathways are favoured or even created. Finally, it remains to be seen whether the numerous responses to kinetin are independent, or whether they all derive from a single 'master' reaction.

We wish to thank Prof. D. J. Carr for obtaining facilities for the work, and for many stimulating discussions of the problems.

TRANSPIRATION PHENOMENA IN DETACHED LEAVES

By Dr. A. J. WILLIS, Prof. E. W. YEMM and S. BALASUBRAMANIAM
Department of Botany, University of Bristol

MANY observations have been made[1–7] which indicate that pronounced changes in transpiration rate of leaves may occur when they are severed from the plant. Often there is a temporary increase in transpiration rate; but under some conditions there is a decrease in rate from the moment of excision.

Two contrasted explanations have been advanced to account for the increase in rate resulting from leaf excision: the first by Darwin and Pertz[2], who attribute the rise in transpiration rate to a temporary stomatal opening which precedes the closure in the later stages of wilting, and the second by Iwanoff[8], who regarded the release of water stress in the conducting system, a feature earlier noted by Dixon[9], as of primary importance, leading to an increase of water supply to the leaf. The experimental studies recently reported in *Nature* by Rufelt[7] have been interpreted by him as favouring the views of Iwanoff; but no direct information is reported regarding the behaviour of the stomata in these experiments.

Many investigations of the transpiration rate of detached leaves carried out in this laboratory indicate a close relationship of stomatal behaviour and transpiration in a range of plants under conditions resulting in a temporary widening of the stomatal apertures as well as under conditions when the leaves have a substantial water deficit and stomatal closure begins immediately the leaves are severed. Stomatal apertures have been studied by several techniques (Lloyd's strips[10], Knight porometer[11], Wheatstone bridge porometer[12]) and transpiration rates by means of a quick weighing procedure and by a hygrometer method. The observations made by the use of these various techniques were found to agree closely.

Two illustrative sets of results are quoted here. Both of the experiments cited relate to normally watered plants and the same procedure was followed. A fully expanded (but not senescent) leaf was enclosed in a 'Perspex' chamber through which was passed a constant stream of air containing 0·0377 per cent carbon dioxide (by vol.) and of 26 per cent relative humidity at 23° C. The outflowing stream (flow rate 1 l./min) was passed over the sensing element of a moisture meter (Shaw, Bradford) and the relative humidity assessed (the capacitance of the dielectric layer of the element varies with its moisture content, and this variation is indicated by the meter readings). Measurements of the carbon dioxide content of the outflowing air stream were also made, an infra-red gas analyser (Howard Grubb Parsons) being used. At the same time that records were taken of the moisture and carbon dioxide content of the outflowing-gas stream, measurements of the resistance of the leaf to gaseous flow were made by means of a Wheatstone bridge type porometer. A detachable porometer cup[13] allowed the surface of the leaf to be swept freely by the air stream between readings.

The results of an experiment on broad bean (*Vicia faba* var. Giant Seville Longpod) are shown in Fig. 1. After a period in darkness, when leaf resistance to gaseous flow was steady and high, and transpiration rate was low, the leaf, still attached to the plant, was illuminated by means of a water-cooled Osram reflector lamp giving an intensity

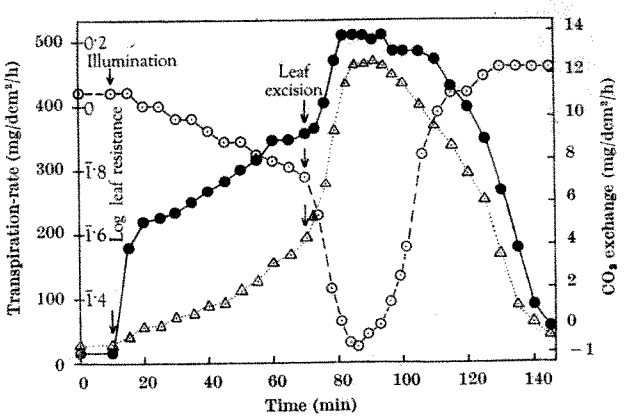

Fig. 1. Effect in *Vicia faba* of leaf excision on rates of transpiration and photosynthesis and on the leaf resistance to gaseous flow. Log. leaf resistance is expressed (as also in Figs. 2 and 3) in Gregory and Pearse units (ref. 14) and refers to an area of 38·5 mm²
△, Transpiration rate; ●, rate of carbon dioxide exchange; ⊙, leaf resistance. The times when the leaf was illuminated and severed are indicated by the arrows

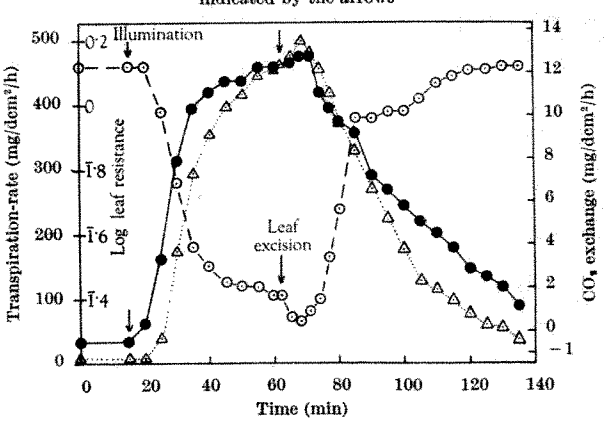

Fig. 2. Effect in *Pelargonium* × *hortorum* of leaf excision on the rates of transpiration and photosynthesis and on the leaf resistance to gaseous flow
See Fig. 1 for explanation of symbols

of approximately 1,650 ft.-candles. The results show that on illumination there was a progressive decrease in leaf resistance, a fairly steady rise in transpiration and an increasing rate of photosynthesis after a very quick initial rise. When the leaf had been illuminated for 1 h the petiole was severed. As shown (Fig. 1), excision of the leaf resulted in a sharp fall in leaf resistance, indicative of stomatal opening, and corresponding rises in both transpiration rate and rate of photosynthesis. After about 20 min from the time of cutting, the leaf resistance begins to increase and the transpiration rate to decline; after a further hour the leaf resistance and transpiration rate were fairly similar to those at the start of the experiment.

A comparable experiment on *Pelargonium* × *hortorum* gave results illustrated in Fig. 2. Here the trends of change were the same as for the broad bean, but the magnitude of the temporary decrease in leaf resistance on excision was neither so great nor was the decrease so prolonged. Nevertheless, there was a corresponding temporary increase in transpiration rate and in photosynthetic rate, results suggestive that the rates were both limited, under these experimental conditions, by the stomatal apertures.

In both the experiments described the effect of leaf excision was to accelerate very markedly the opening of stomata, which was already occurring as a result of illumination. It may be suggested that the basis of the mechanism of stomatal movement is the same under these different conditions, the stopping of the water supply to the leaves having a quicker effect on the balance of turgor of the epidermal and guard cells than a photo-induced change. The importance of the water relations of the leaf during normal stomatal opening in the light has already been noted[15].

One feature of considerable importance with regard to the occurrence, in detached leaves, of the temporary stomatal opening and increase in transpiration rate is the water deficit of the leaves at the time of excision. When the deficit is small the increase in transpiration rate is large, but when water stress is severe at the time of cutting there is a progressive decrease in transpiration rate and no evidence of any temporary opening of stomata. Studies made by Miss J. M. Marshall in this laboratory in 1954 on *Vicia faba* by means of a Knight porometer indicated that provided the leaf water deficit[15] was not greater than 11 per cent a temporary decrease in leaf resistance to gaseous flow was usually obtained on severance of the petiole; it was also found that the time taken for the stomata to open and then close to the degree of opening at the time of excision was longer the lower the water deficit. More recent investigations have confirmed these findings; representative results are shown in Fig. 3. Illuminated leaves of little deficit (approximately 2 per cent), moderate deficit (10·7 per cent) and considerable deficit (20 per cent) were severed from the plants after the leaf resistance had reached a fairly steady value (measurements made by Wheatstone bridge type porometer; an air-stream of approximately 33 per cent relative humidity at about 23° C was passed at 2 l./min over the leaves). Fig. 3 indicates that, on leaf excision, there was a substantial temporary stomatal opening in the leaf which was almost fully turgid, a small stomatal opening in the leaf of moderate water deficit but progressive closure of stomata in the leaf of high water deficit. Other experiments show that the changes in leaf resistance are paralleled by changes in transpiration rate, and that the phenomena reported occur also in leaves in darkness. It is of note that under conditions of high water stress the phenomenon of increased transpiration rate is least evident or not shown at all, whereas the Iwanoff effect might be expected to be greatest in these circumstances.

The changes reported by Rufelt[7] of the transpiration rate of leaves of aspen repeatedly taken from and brought into contact with water are explained by him on the basis of the Iwanoff theory. Under similar conditions, however,

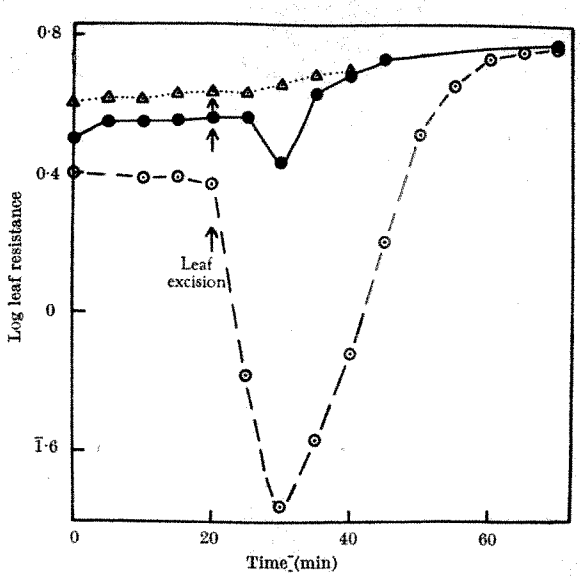

Fig. 3. Changes in resistance to gaseous flow in excised leaves of *Vicia faba* of different water deficits. Leaf of: ⊙, about 2 per cent deficit; ●, 10·7 per cent deficit; △, 20 per cent deficit

there is evidence[5] that in *Pelargonium* stomatal changes are related to changes in transpiration rate; furthermore, we have found that if water is made available to wilted leaves of *Pelargonium* that there is usually at first a decrease in transpiration rate, associated with increasing leaf resistance, and that later there is an increase in transpiration (and photosynthesis) associated with stomatal opening. It may also be noted that if leaves of, for example, *Vicia faba* are cut under water, normally a decreased transpiration rate is at first observed, a result at variance with the view that increased water supply to the leaf leads to an increased transpiration rate.

The results outlined above show that in many instances changes in transpiration rate of excised leaves are mediated by stomatal movements, doubtless arising from differential turgor changes in the epidermal and guard cells. Differences in quantity of osmotically active substances in these cells may to some extent result in differences in both uptake and loss of water, and changes in stomatal apertures are not unexpected when conditions of water supply to leaves are altered. Release of tension in the conducting system clearly occurs when leaves are severed, but the evidence briefly presented here indicates that it is not the release of water tension *per se* which results in changes in transpiration rate but the direct and indirect effect of this release on the turgor relations of the epidermal and guard cells, changes in turgor leading to changes in stomatal apertures and so influencing transpiration rate. The rapid change in the conditions of water supply to the leaf probably leads to a quick and pronounced displacement of the dynamic equilibria of water relations of the cells of the leaf, notably the guard cells and epidermal cells, so resulting in the phenomena observed.

LETTERS TO THE EDITOR

ASTROPHYSICS

Occultation Theory of Jovian Radio Outbursts

It has been suggested by Strom and Strom[1] that the sporadic decameter radio energy attributed to the planet Jupiter does not actually originate on that body, but comes rather from a distant background of discrete sources or 'radio stars'. According to the Stroms, the Jovian ionosphere could act as a gigantic spherical lens to focus energy on the Earth when these discrete sources are temporarily occulted by Jupiter. This theory is rendered more plausible by the work of Grossi, Strom and Strom[2], which shows that the ionosphere of the Earth itself may behave as such a lens in the frequency region of 5–30 Mc/s. The well-established correlation of the Jovian outbursts with the rotation of that planet is explained as a result of a magnetic field, tilted with respect to Jupiter's axis of rotation, which is presumed to introduce a periodic modulation in the focusing mechanism.

It is evident that if this theory is correct the observed durations of the noise storms should show a marked correlation with the apparent angular speed of Jupiter relative to the background of fixed stars. From an examination of 16 outbursts recorded by Douglas[3] during the period 1957–60, Strom and Strom concluded that such an effect did in fact exist. Recently, we have completed an analysis of our own observations of the 1961 apparition of Jupiter. Fig. 1 is a plot of the durations of 129 noise storms observed at a frequency of 18 Mc/s during this apparition. For comparison the angular speed of Jupiter on the celestial sphere is shown in the upper part of the figure. There does not in this case appear to be a systematic relationship between angular speed and noise storm duration, and this is particularly evident if one disregards the period of December 1–March 15, when the planet was too close to the Sun for reliable decametric observations to be made.

If the noise storms should result from occultations, it would further seem logical that the rate of occurrence of the storms should decrease as the angular speed of Jupiter decreases, perhaps approaching zero near the stationary points of May 26 and September 24, when the planet was motionless with respect to the celestial sphere. Fig. 1 shows that, on the contrary, the greatest concentration of noise storms occurred near the May 26 stationary point. There does not appear to be any systematic relationship between Jupiter's angular speed and the time-density of the radio noise storms.

Our flux measurements show that at frequencies greater than 17 Mc/s the Jovian radiation has a spectral index of less than -5 (that is, as the frequency, f, increases, the flux density falls faster than f^{-5}) (ref. 4). On the other hand, the great majority of the discrete sources have spectral indices ranging from $-0{\cdot}6$ to $-1{\cdot}2$. One might argue that the added steepness of the Jovian spectrum is due to frequency sensitivity of the focusing mechanism, analogous to the optical phenomenon of chromatic aberration, but in this event the relative intensities of the different frequencies should vary with the Earth–Jupiter distance, an effect that does not seem to be present in our data.

Our measurements also indicate that the Jovian flux density occasionally approaches 10^{-19} W/m²/c.p.s. at 18 Mc/s and that bursts having an intensity of 10^{-20} W/m²/c.p.s. are relatively common. Since Strom and Strom believe that the focusing mechanism yields a maximum power gain of about 1,000, their theory would seem to require the presence of a dense background of discrete sources producing individual 18 Mc/s flux densities of 10^{-22}–10^{-23} W/m²/c.p.s. During the time-interval shown in Fig. 1, the disk of Jupiter swept out an area of sky of approximately 0·37 square degree. If each of the noise storms in the figure represents an occultation, then the density of these rather strong sources must be of the order of 129/0·37 = 344 sources per square degree. (This figure is perhaps conservative, rather than otherwise, since it may well be that the occultations would have to be nearly central for reasonable power gains to be realized.) Actually, of the several thousand discrete sources that have been catalogued, relatively few are known to produce 18 Mc/s fluxes of the required intensity. If sources of large angular subtense are excluded, as the occultation theory requires,

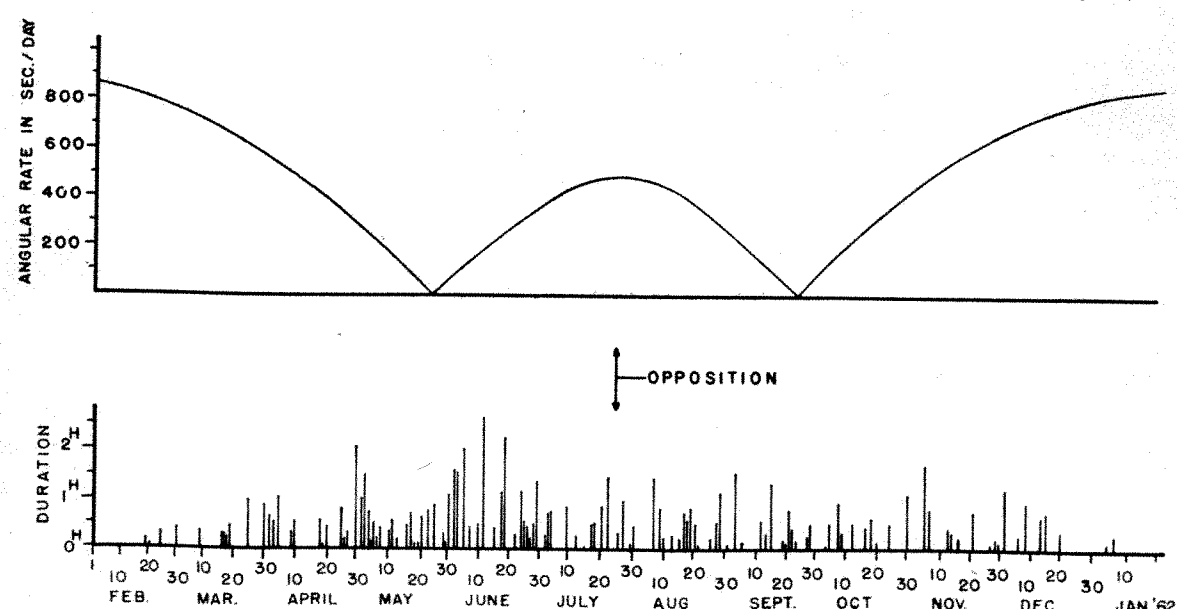

Fig. 1. Duration and time density of Jovian noise storms at 18 Mc/s during the 1961 apparition, compared with the planet's apparent angular speed

this number is still further reduced. By assuming a mean spectral index of $-1{\cdot}0$, a rough estimate of the 18 Mc/s source population can be obtained from the source density figures derived from Mills's 100 Mc/s survey[5]. The predicted density of sources having an 18 Mc/s flux greater than 10^{-23} W/m²/c.p.s. is only about two per steradian in the portion of the sky traversed by Jupiter during the 1961 apparition. While scintillation may affect somewhat the amplitudes of the Jovian bursts, it seems unlikely to alter in an essential way the orders of magnitude that are involved.

As a result of these discrepancies we have been led to conclude that our observations do not lend support to the occultation theory of the Jovian radio outbursts.

Frequency Drift and Time Profile of 200 Mc/s Bursts of Type III and the Electron Temperature of the Corona

The most prominent feature of solar bursts of spectral type III is their frequency drift from higher to lower frequencies. Wild[1] has determined the drift velocity in the frequency region of 70–130 Mc/s, but until now there have been no satisfactory determinations of the drift rate on higher frequencies.

We therefore undertook to determine the frequency drift velocity of type III bursts from high-resolution swept frequency observations made in the 205–230 Mc/s range at the Oslo Solar Observatory between the middle of 1961 and late 1962.

Fig. 1 gives a histogram showing the distribution of bursts of different drift velocities. The curve has a maximum around -40 Mc/s² and a tail which extends to roughly -150 Mc/s². It is noteworthy that no bursts were observed with frequency drift velocities less than -20 Mc/s². The total number of bursts which were included in the analysis amounted to 68. The mean drift velocity as calculated from the histogram is $\mathrm{d}f/\mathrm{d}t = -60 \pm 10$ Mc/s².

In his observing range, Wild[1] found that the frequency drift velocity was approximately proportional to the frequency, and was given by $\mathrm{d}f/\mathrm{d}t = -f/k$, where k was a constant which varied from one burst to the next one. The mean value of k determined from 10 bursts was 4·5 sec. Inserting our observed mean value of $\mathrm{d}f/\mathrm{d}t$ in Wild's empirical equation, and using 215 mc/s as the centre frequency of the observing range, we find $k = 3{\cdot}6 \pm 0{\cdot}6$. This is relatively near the value found by Wild, but indicates that k decreases with increasing frequency. It is interesting to note that the observed variation of k agrees closely with that expected for an exciting disturbance propagating at constant speed in a corona in which the electron density follows Newkirk's[2] model for an active region.

The time profiles of the bursts in our observational material have been found from photometer tracings along the time axis of the records. For this purpose only distinct bursts, in which the maximum intensity did not saturate the records, were selected. The mean time profile of the bursts was slightly asymmetrical, and had a rising part which was steeper than the decaying portion.

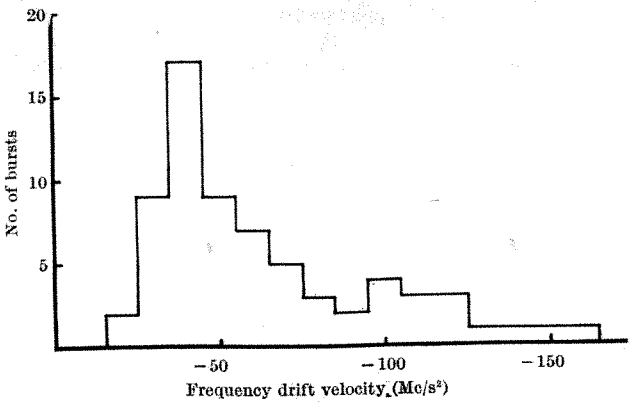

Fig. 1. Distribution of bursts of different frequency drift velocities

We now adopt the conventional model of type III bursts. The bursts are generated by a disturbance travelling at high speed through the corona, exciting oscillations with frequencies which are determined by the plasma frequencies at the appropriate heights. The oscillations are damped by collisions between electrons and ions. The time profile as observed on a single frequency can then be calculated in the manner outlined by de Jager[3]. The factors of importance for the calculated profile are the frequency drift velocity, the band-width of the excited oscillations and the collision frequency between electrons and ions. Using a frequency drift of -60 Mc/s², we found excellent agreement between the observed and the calculated time profile for a half-power band-width of 28 Mc/s and a collision frequency of 8 per sec. The large band-width agrees with the impression we get from a visual inspection of the records. The natural band-width of electron oscillations in the solar corona seems to be small, and it is therefore reasonable to suppose that the observed band-width is determined by the dimensions of the exciting disturbance. Using Newkirk's model of the variation of electron density with height in an active region, we find from our observations that the depth of the exciting disturbance at a height of $1{\cdot}15\ R_\odot$ is about $0{\cdot}05\ R_\odot$.

From a similar analysis of the time profiles of type III bursts observed by Weiss and Sheridan[4] at 40 Mc/s we find evidence for an expansion of the exciting disturbance as it travels out through the corona. If the disturbance is assumed to be a cloud of particles, expansion would occur if the particles were ejected with an initial velocity dispersion.

When the electron density and the collision frequency are known, the electron temperature can be determined. The value of 8 per sec for the collision frequency gives $2{\cdot}1 \times 10^6$ deg. K for the electron temperature at the height of $1{\cdot}15\ R_\odot$. This is in good agreement with a streamer temperature of $2{\cdot}3 \times 10^6$ deg. K as found by Hepburn[5] from optical eclipse observations.

GEOPHYSICS

Particle Sampling from Noctilucent Clouds

PARTICLE sampling experiments have been conducted at the mesopause region of the atmosphere. The experiments utilized sounding rockets which were fired from the Kronogård range (66° N, 19° E) in northern Sweden, during the summer of 1962. Two successful flights out of a total of four firings were achieved: one (August 11, 0140 G.M.T.) in the presence of noctilucent clouds and one (August 7, 0047 G.M.T.) when no such clouds could be visually observed from the ground and from aircraft. The *Nike-Cajun* rockets carried identical instruments and in so far as can at present be determined the experimental conditions of the two successful flights were similar.

The experimental apparatus consisted of sampling surfaces mounted in two cylindrical containers symmetrically mounted about the longitudinal axis of the rocket at the forward end of the payload. Four high-purity collection surfaces: (1) nitrocellulose film with coating of aluminium; (2) nitrocellulose film coated with fuchsin dye; (3) indium-coated 'Lucite'; (4) calcium film with a thin protective coating of aluminium, paraffin and silicone oil, were mounted in each container. The different surfaces were intended to retain non-volatile particles or portions of particles for laboratory analysis as well as to indicate whether volatile particles or coatings had been deposited. To minimize contamination from terrestrial particles and to aid in the identification of such contaminants, techniques similar to those used in previous rocket samplings were used[1]. The primary controls consisted of areas which were shielded from particles moving in ballistic trajectories but not from laboratory particles.

From previous experience[2] the period August 1–20 was chosen as the most favourable time for observing noctilucent clouds at the firing-range location. During the twilight hours the sky was visually patrolled by trained observers (ground-based and airborne) 150 km to south where the conditions for viewing the phenomenon, if present over the rocket range, were optimum. Photographs were obtained of the clouds through which the second rocket was fired.

The collection surfaces were exposed at an altitude of approximately 75 km by the spring ejection of an outer rocket-nose tip. A second spring mechanism closed the sampling ports at the forward end of the nose cone and vacuum-sealed the containers which held the surfaces. This latter action occurred at an altitude of approximately 95 km while the rocket was still ascending. No attempt was made to sample during the descent of the rocket. The containers from the successful flights were recovered sealed and in excellent condition within an hour after the firings.

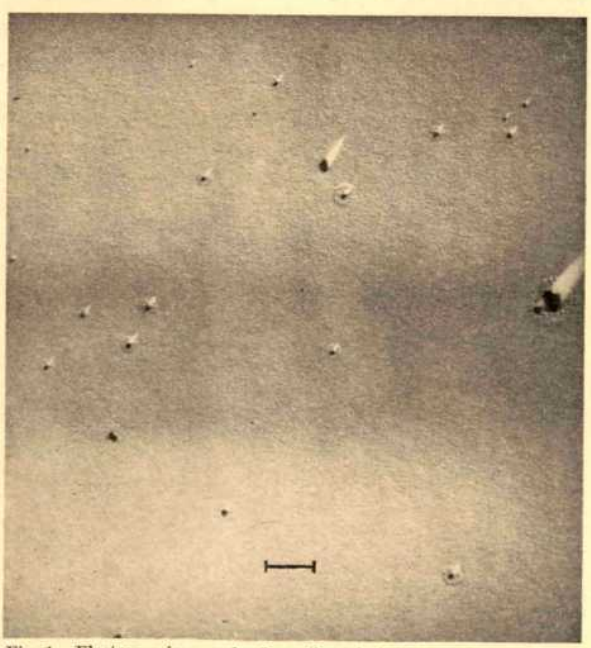

Fig. 1. Electron micrograph of noctilucent cloud particles on a nitrocellulose film which is about 200 Å thick and has had an evaporated coating of aluminium applied before collection and was shadow-cast with chromium afterwards (scale = 1μ)

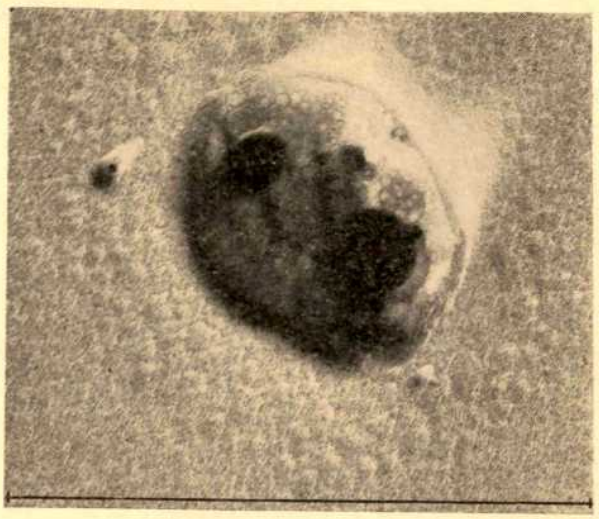

Fig. 2. Electron micrograph of a noctilucent cloud particle on a substrate prepared as in Fig. 1 (scale = 1μ)

After the flights, the gas in the containers was examined mass spectroscopically to determine if any volatile products foreign to the lower atmosphere had been obtained. Outgassing and leakage would be expected to mask slight concentration changes of gases or vapours normally found in the sea-level environment. Only traces of alcohol and acetone, which were both used in the cleaning operations, were detected by this technique.

The collection surfaces from the two flights show significant differences. The first and most apparent difference is that the nitrocellulose films from the cloud flight contain non-volatile particles the numbers per unit area of which are greater by two to three orders of magnitude than the surfaces from the non-cloud flight and the contamination level as determined from the control areas. These cloud particles are primarily in the size-range 0·05–0·5μ in diameter. Preliminary electron microscopic scanning indicates that in this size-range there exists an integral distribution function of the form $N \propto d^{-p}$, where p lies between 3 and 4. However, there appears to be a distinct cut-off in the power distribution for particles smaller than about 0·05μ. The cut-off size varies somewhat with sample position. The number of particles and the observed size distribution are in agreement with the observed light scattering properties of the clouds[3]. A significant percentage of the particles as seen on the nitrocellulose substrate are surrounded by a circular pattern. Some typical particles and patterns can be seen in the low-magnification electron micrograph shown in Fig. 1. The higher magnification electron micrograph (Fig. 2) shows the details of one large particle surrounded by such a pattern. Preliminary evidence indicates that this pattern was caused by a volatile coating evaporated from the particle after deposition and that this coating was ice. A number of the particles found on the surfaces recovered from the non-cloud flight show distinct similarities with those obtained from the cloud flight and from a previous rocket sampling at higher altitudes[1]. There is, though, no evidence of ring patterns surrounding any of the particles from these non-cloud flights. Fig. 2 also shows dark spherical inclusions in the particle which are opaque to 100-keV electrons. This feature is observed in a large number of the particles.

On prolonged intensive electron bombardment it is found that these opaque inclusions are by far more stable than other portions of the particles. Composition analysis using an electron beam microprobe has been started and yields evidence of iron and nickel. Further, some of the particles give a consistent electron diffraction pattern which has as yet not been identified.

Statistical and composition analysis is continuing. A more detailed description of these experiments and the quantitative information gained from them will be presented in the near future. A programme for similar experiments to measure other parameters (for example, particle concentration as a function of altitude) associated with the clouds is at present being formulated.

The rocket flights and analysis described here have been a joint undertaking of our institutions under the international sponsorship of the Swedish Space Committee and the U.S. National Aeronautics and Space Administration. The success of the programme is due to the co-operation of many American and Swedish individuals and organizations too numerous to fully acknowledge in this communication.

Retention of Radiogenic Argon in Glauconites from Proterozoic Sediments, Northern Territory, Australia

Three glauconite concentrates from Proterozoic sediments of the Carpentaria region of the Northern Territory which have been dated by the potassium–argon method show that there is almost complete retention of radiogenic argon in these samples when compared with control ages by the potassium–argon and rubidium–strontium methods on micas and whole-rock samples.

Previous potassium–argon determinations on glauconites have shown that many of the measured ages are too young by amounts ranging up to, and in some cases exceeding, 20 per cent[1,2]. Evernden *et al.*[1] showed that there is generally, but not universally, an argon-loss pattern dependent on the depth of burial. On the basis of general agreement between potassium–argon and rubidium–strontium results on glauconites Hurley[2] concluded that argon leakage may not be wholly responsible for the young ages; but rather that some mechanism of slow structural development of the crystal lattice has occurred, which has resulted in an increase of potassium content with time. Russian workers have dated large numbers of Proterozoic glauconites, and, although independent control of these ages usually has not been possible, Polevaya *et al.*[3] regard glauconite dating as 'largely successful'. There have been no reports of potassium–argon dates older than the age of the sediments in which they occur; this provides further support for the accepted view that glauconites are of authigenic origin.

A report on the regional geology of the Carpentaria region is in preparation by officers of the Bureau of Mineral Resources[4]. Proterozoic sediments, ranging from 13,000 to 45,000 ft. thick, crop out over an area exceeding 50,000 square miles adjacent to the west coast of the Gulf of Carpentaria. The sediments are mainly well sorted, shallow water, shelf deposits, even in those areas where the maximum thickness is developed. The almost complete absence of detrital minerals, other than quartz, suggests that deposition occurred very slowly in a shallow, slowly subsiding basin. Volcanic rocks are present in minor amounts throughout the sequence. Subsequent folding over the whole area has been slight; dips commonly are less than 10°, but locally may be as high as 60°. Since the Precambrian, only a few hundred feet of flat-lying Cambrian(?) and Mesozoic sediments have been deposited.

The Proterozoic sediments are divided into three groups, which from oldest to youngest are the Tawallah, McArthur and Roper Groups. Two of the glauconite samples (*GA*753, *GA*754) are from the Aquarium Formation (Calvert Hills sheet 1 : 250,000 *SE* 53–8), a unit which is about 1,200 ft. below the top of the Tawallah Group in this area. The third sample (*GA*752) is from a locality, 120 miles to the north-west, in the Rosie Creek Sandstone, which is probably stratigraphically equivalent to the Aquarium Formation[5]. The estimated maximum overburden for *GA*753 and *GA*754 is about 2,500 ft., and that for *GA*752 is in excess of 15,000 ft.[5].

Control as to the maximum possible age of the sediments is provided by the age of 1,780 m.y. for the Norris Granite[6], which is unconformably below the Tawallah Group. A younger limit is given by the maximum age of 1,480 m.y. ($\lambda_{Rb} = 1{\cdot}39 \times 10^{-11}$ yr^{-1}) for the Packsaddle Microgranite[6], which intrudes the Tawallah Group and is believed to have been a feeder to a volcanic member (Hobblechain Rhyolite) in the uppermost formation of this Group.

All three concentrates consisted of discrete dark green pellets of glauconite in the size-range 0·1–0·3 mm. They were contaminated by up to 10 per cent of hæmatite-encrusted quartz with similar specific gravity and magnetic properties to the glauconite, thereby rendering beneficiation difficult. They were free from detrital micas and feldspars. An attempt was made to remove some of the impurities from *GA*754 by splitting the sample into two fractions, *A* and *B*. Fraction *A* was washed in warm 0·1 N hydrochloric acid. Potassium was determined by flame photometry as described by Cooper[7]; weighings were made from 1-g splits of the concentrates, which were pulverized. Argon determinations were made on splits of about 0·2 g by isotope dilution as previously described[8], the only modification being that the line was baked at 130°–160° C instead of the usual 270° C.

Table 1. Potassium–Argon Results on Glauconites from Proterozoic Sediments, Northern Territory

Sample No.	Potassium analyses (wt. per cent)	Average potassium (wt. per cent)	$^{40}Ar^*/^{40}K$	Atmos. ^{40}Ar (%)	Calculated Age (m.y.)
GA 752	7·16, 7·14	7·15	(1) 0·1369	1·4	1,523
	7·16, 7·14	7·15	(2) 0·1366	1·5	1,521
GA 753	5·81, 5·82	5·82	0·1304	1·8	1,473
GA 754	*A* 6·52, 6·51	6·52	(1) 0·1450	1·4	1,584
	A 6·52, 6·51	6·52	(2) 0·1411	1·1	1,555
GA 754	*B* 6·43, 6·43	6·43	(1) 0·1436	0·8	1,573
	B 6·43, 6·43	6·43	(2) 0·1473	1·7	1,601

$^{40}Ar^*$, radiogenic component. $\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr^{-1}; $\lambda_k = 0{\cdot}584 \times 10^{-10}$ yr^{-1}; $^{40}K = 1{\cdot}22 \times 10^{-4}$ g/g K.

Sample localities:
GA 752: 15°55′ S, 135°40′ E, Rosie Creek Sandstone.
GA 753: 17°18′ S, 137°22′ E, Aquarium Formation.
GA 754: 17°28′ S, 137°39′ E, Aquarium Formation.

Results are given in Table 1. Duplicate potassium analyses agree to within 0·5 per cent, and duplicate argon results agree to better than 2 per cent. Polevaya *et al.*[3] suggested that because of the cation exchange properties of glauconites, a small amount of potassium in the mineral may be loosely adsorbed on the surface of the pellets. They showed that this potassium may be removed by treating the sample in dilute hydrochloric acid (0·05–0·1 N) without causing any loss of radiogenic argon. From Table 1 it is seen that the potassium content of *GA*754 actually increased, which suggests that removal of impurities occurred rather than removal of loosely held potassium. The results indicate that the acid washing

of sample *GA754 A* has had little or no effect on the measured age.

Glauconites *GA753* and *GA754*, from the Aquarium Formation, yield ages of 1,475 and 1,580 m.y. respectively, and sample *GA752* from the Rosie Creek Sandstone has a measured age of 1,525 m.y. It may have been expected that *GA753* and *GA754* would give similar ages, whereas *GA752* would yield a lower age because of its greater depth of burial. If it is assumed that the measured age for *GA754* is close to the true age of the Aquarium Formation then *GA753* has retained 93·5 per cent of its radiogenic argon, and *GA752* has an argon retentivity of 96·5 per cent, provided that the correlation of the Rosie Creek Sandstone with the Aquarium Formation is correct. The ages correspond to the lower part of the Middle Proterozoic according to the time-scale of the Geological Survey of Canada[9], and to the Lower Proterozoic according to the present Russian time-scale[10,11].

The measured ages of the glauconites are consistent with the control ages obtained on the underlying Norris Granite (1,780 m.y.) and the intrusive Packsaddle Microgranite (1,480 m.y.). Field observations indicate that the Packsaddle Microgranite probably acted as a feeder to the Hobblechain Rhyolite in the upper part of the Tawallah Group. There is no evidence of a hiatus between the deposition of the Aquarium Formation and the extrusion of the Hobblechain Rhyolite. Hence, the age of 1,580 m.y. for sample *GA754* may indicate that sedimentation in this area was extremely slow, which supports the conclusion reached independently from geological observations. The results show that under certain conditions it is possible to obtain reliable ages on Proterozoic glauconites. The discrepancies found by other workers[1,2] on glauconites of Palæozoic and younger age may be caused, in part, by other factors besides depth of burial and the slow increase of potassium with time. Many of these younger samples are from rocks which, although not actively involved in orogeny since their deposition, occur in generally unstable areas. Our samples, and much of the Russian material, come from very stable cratonic regions, and it is suggested that the tectonic history of the region may have an important bearing on the degree of argon retention in glauconites.

Note added in proof. Richards[12] has reported an isotopic analysis of lead from a galena (Pb-69) from the McArthur Group, which overlies conformably the Tawallah Group. This galena is thought to be of syngenetic origin. The preferred model age of the lead is about 1,560 m.y.; this is broadly consistent with the glauconite ages. Hence, now it is unnecessary to regard the lead as anomalous.

The samples were collected by geologists of the Bureau of Mineral Resources, and the age measurements were made in the Australian National University. The glauconite was separated by R. Rudowski. We thank H. G. Roberts for helpful discussions.

PHYSICS

Simultaneous Sampling of Cosmic Radiation at Different Altitudes

A technique has been used with limited success to obtain simultaneous measurement of cosmic radiation at two different altitudes.

The method consists of suspending two packets of nuclear emulsion plates from the one balloon, while maintaining a constant vertical separation of 10,000–27,000 ft. between the packets. The separation has been maintained throughout level balloon flights of up to 4 h duration. This technique is of value in the investigation of the variation of cosmic radiation with height, as in this way the two packets do not separate in latitude and longitude—a factor which enters if two separate independent balloons are flown.

This has been achieved by carrying aloft a cone of nylon string which was allowed to unwind at a predetermined height, leaving one packet of plates suspended at the balloon while the other fell at the end of the string. Using 840 denier twisted nylon string of 10-lb. breaking strain, success has been limited to 'drop-off' loads of less than 300 g. The expansible balloons used were kept at a constant pressure-level for periods of up to 4 h by the use of a mechanical valve as described by Hopper and Laby[1].

The balloon train, as it leaves the ground, is as illustrated in Fig. 1, with the lower section (below the dotted line) being dropped off at the pre-determined height. Radar corner reflector targets at the balloon and on the released section have been necessary to obtain records of both emulsion packets, and to facilitate recovery of emulsions and nylon string. Tracking has been carried out using a 277 *Q* 10 cm radar set. A typical altitude-time record of a successful flight is shown in Fig. 2.

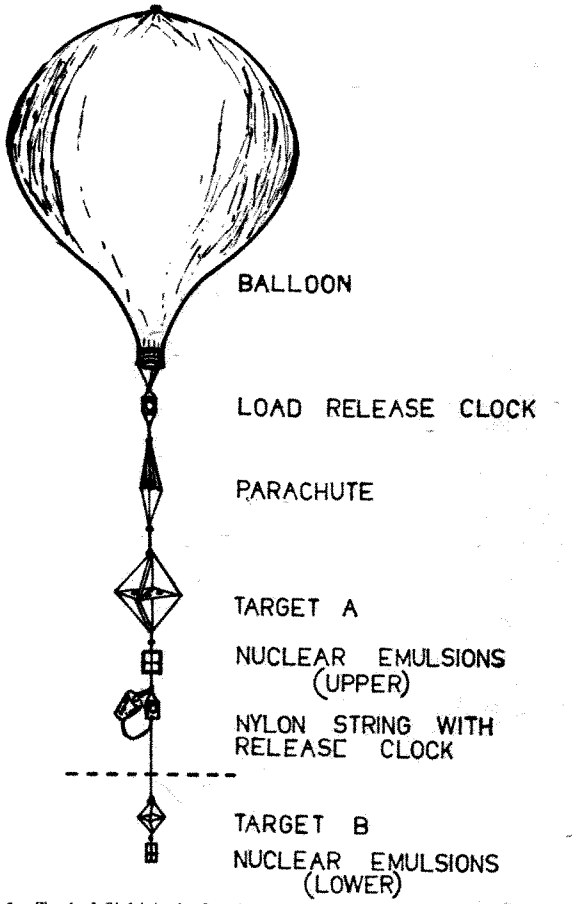

Fig. 1. Typical flight train for simultaneous cosmic ray measurements at different altitudes

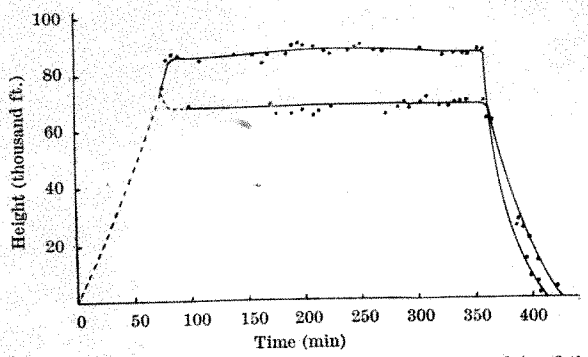

Fig. 2. Flight curve of March 29, 1962, showing radar plots of the two targets separated by 20,000 ft. 1,750 g balloon; released 9 a.m.

The nylon string is wrapped tightly in polythene sheeting to exclude moisture and prevent freezing during the ascent and also to prevent the nylon falling off the cone before it is released by its alarm clock, say 75 min after release of the balloon from the ground. As the alarm rings, the alarm winder releases the key (Fig. 3) holding the lower packet and target, which then fall away freely, unwinding the string in the process. Twenty thousand feet of string unwinds in approximately 10 min.

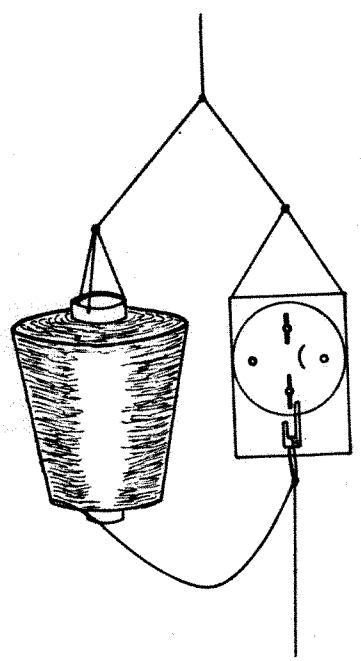

Fig. 3. Nylon string with release clock

A series of 30 flights, using nylon strings, undertaken to develop and test this technique has yielded 7 known successes. Of the remainder, only about 30 per cent are certainly failures of the string to hold the load during the fall or at the end of the fall. A further series of 10 flights using polyethylene monofilament string has yielded only two partial or limited successes and tests with this string have been discontinued.

Details of materials and conditions which have so far led to success with this technique are as follows: balloons used, 800, 1,750 and 2,400 g 'Darex'; string, nylon 840 denier, twisted; string-length, 10,000–27,000 ft.; total load dropped off, up to 300 g; height of release, 60,000–80,000 ft.; corner reflectors, target *A*, 30 in. double: target *B*, 12 in. double; wind at height of release, less than 15 knots.

One of the major difficulties encountered has been that of obtaining sufficient lengths of unbroken string and ensuring that, where knots are unavoidable, they are tied and glued in such a way that they achieve a high percentage of the strength of the unbroken string.

It is of interest to note that in several instances, although the string was intact during the level portion of the flight, it broke after the parachute was released and the two packets fell freely to the ground.

It seems highly probable that much greater loads could be dropped off with proportionally heavier string and the technique extended to sampling at three or more heights simultaneously. This would probably necessitate use in uninhabited regions where a greater breaking strain nylon would not become a hazard when it is eventually released from the balloon. Further applications might be found if heavier string permits the dropping of the necessary telemetry equipment to make simultaneous meteorological soundings.

We thank Mr. F. Alexander and Mr. W. Thornton, of British Nylon Spinners, Victoria, for their assistance, and the Australian Bureau of Meteorology, for use of radar facilities.

Ball Lightning

Ball lightning has been described[1–3] as an approximately spherical mass of plasma about 20 cm diameter, moving at 2 m sec^{-1} or less, sometimes rotating, emitting bright radiation, having a lifetime of a few seconds or less and sometimes disappearing explosively.

Various explanations of these phenomena have been put forward[4,5], and I now suggest that the lightning ball consists of a plasma vortex ring. Vortex rings are hydrodynamically stable[6] and are easily produced, for example, as smoke rings. Plasma vortex rings have been observed in the laboratory for a few microseconds[7,8] and rotating plasmas[9] have been studied as a means of storing electrical energy in a "hydromagnetic capacitor".

If the plasma possesses vorticity $^6\zeta$, a vortex of radius r_0 has a strength k of $\zeta r_0^2/2$. Then a vortex ring of minor radius r_0, major radius α moves with velocity $k/(2\ \alpha)$ parallel to its major axis. The mean angular velocity about the minor axis is k/r_0^2, giving a kinetic energy of the order of $\pi^2\rho\alpha k^2$ for a plasma of density ρ. If the vortex ring is produced from a plasma in a magnetic field, the centrifugal force due to the vorticity is balanced by a magnetostatic pressure[10]. The trapped magnetic field prevents expansion of the ring.

A plasma vortex ring with a translational velocity of 2 m sec^{-1} and major radius of 10 cm has a vortex strength of 4×10^3 cm^2 sec^{-1}. The lightning channel may produce a shock velocity of 10^6 cm sec^{-1}, the resulting gas density being many hundred times that of air at N.T.P. Consequently, the kinetic energy associated with the vorticity can attain a value of a few hundred joules. This energy would produce an appreciable explosion if the field and current distributions were suddenly disrupted, as they might be on collision with a metallic object.

The lifetime of the plasma vortex is controlled by loss of thermal energy and dissipation of the magnetic field. If the plasma temperature is 10^4 °K, a value reported[10] for lightning flashes, the magnetic diffusivity D_m is of the order of 10^{-5} cm^2 sec^{-1} and the time r_0^2/D_m for the field to diffuse out of the ring is greater than 10^5 sec. In addition to kinetic energy, the plasma possesses thermal

and ionization energies amounting to several megajoules. This energy is mainly lost by radiation, at a rate which is initially of the order of 10^7 W. Consequently, the lifetime of the plasma must be a few seconds or less. Viscous dissipation and thermal conduction to the surrounding atmosphere increase the major radius of the plasma vortex ring and reduce its translational velocity.

The vorticity of the lightning ball could be produced impulsively by asymmetric expansion of a lightning stroke, particularly if the stroke occurred in the vicinity of a solid object having an aperture. Reports of ball lightning describe its arrival down chimneys or through a doorway. It is not easy to see how the appropriate field distributions could be set up by such an event but this may be a factor contributing to the rarity of the lightning ball.

Liquid Crystals in an Electric Field

It has long been known that nematic liquid crystals show remarkable orientation effects in electric fields as well as in magnetic fields[1]. We have observed the formation of domains in thin layers of the liquid crystal phase of several organic compounds. Typical results were obtained with *p*-azoxyanisole,

The domains form in electric fields of about 3,000 V/cm. Their appearance and behaviour suggest several properties of liquid crystals which have not previously been reported.

The properties reported here may be observed at any temperature within the range 116°–134° C, over which *p*-azoxyanisole forms a nematic liquid crystal phase. Samples of the material are melted between glass plates the inner faces of which have a transparent conductive coating of tin oxide. Samples 25–100μ thick are observed by unpolarized transmitted light while a voltage is applied between the conductive coatings on the plates. As the voltage is increased from zero, nothing is observed until a critical field strength is reached where parallel domains form as illustrated in Fig. 1. The ragged vertical line near the centre of the illustration is the edge of the conductive coating on one of the glass plates. To the left of this line there is an electric field perpendicular to the plane of the page, and to the right of the line there is no field. The domains are seen in the left half of the picture. They form within a time of about 2 msec after applying the field and disappear in about 20 msec after the field is removed.

Substantially identical domains are observed with either an a.c. or a d.c. field. With a.c. fields the effect is observed for all frequencies below an upper limit which ranges from 15 to 100 kc/s in different specimens.

If the domains are observed with monochromatic light their appearance does not change with changes in wavelength of the light, showing that they are not due to an interference effect. Because the resistivity of the liquid is about 10^9 ohm-cm, the domains could not result from electrolysis or mass transport due to current flow. Since they are seen by transmitted light which is unpolarized, the domains must be regions of differing refractive index. It may be seen from Fig. 1 that there are several sharply bounded areas within which the domains are parallel. At the boundary the orientation changes discontinuously and, in the adjoining area, the domains are still parallel but with the new orientation. The lines separating these areas are present without the field and remain unchanged when the field is applied. Several such lines may be seen in the right half of the picture where they form small closed loops. These lines are the 'threads' which are always observed in nematic liquid crystals and from which the name 'nematic' is derived[2]. The parallel domains within these bounded areas and the sharp changes of orientation on crossing a boundary suggest clearly that the threads are analogous to the crystal boundaries in an ordinary solid polycrystalline aggregate.

This analogy is further illustrated by the behaviour when the liquid is heated above the transition temperature to the isotropic liquid[2] and then cooled until the nematic liquid crystal phase again forms. When the nematic phase first forms there are many such small bounded areas, each with its own orientation as revealed by the domains. Over a period of minutes, these areas coalesce to a small number of larger areas having millimetre dimensions. Within each of these the domains are parallel and uniformly oriented throughout. In the isotropic liquid the individual molecules are randomly oriented, while in the nematic liquid there is a high degree of parallel ordering of the long molecules[3]. It would appear to be a natural consequence of the space-filling requirements of elongated molecules that the transition from the isotropic phase to the ordered nematic phase results in adjacent areas of differing orientation.

Experiments are still being carried out to elucidate the structure which gives rise to the domains. Tentative results indicate that the domains result from forces of the same general kind which give rise to domains in ferroelectric crystals, that is, cancellation of persistent internal polarization by polarization reversal in neighbouring

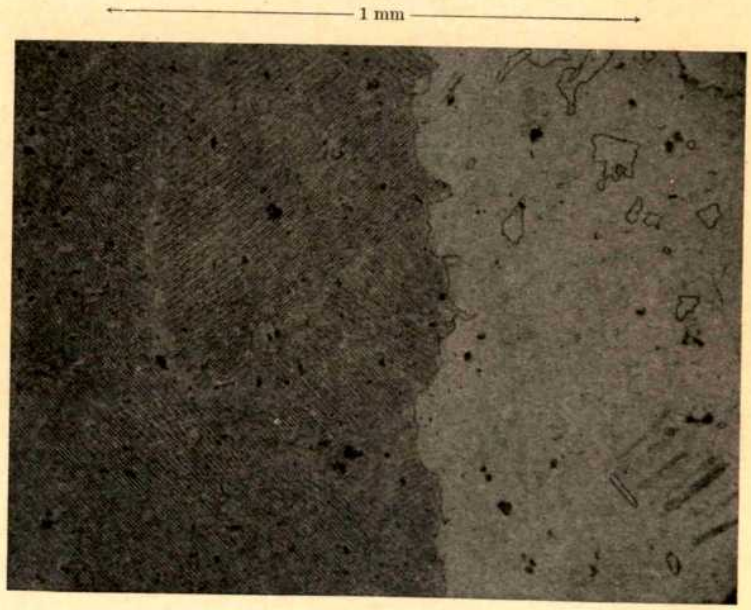

Fig. 1. Domains formed in liquid crystal phase of *p*-azoxyanisole by applying a 1 kc/s a.c. electric field of 3,000 V/cm in a direction perpendicular to the plane of the page. Further details of the experiment are given in the text

volume elements. Such polarization must necessarily be small since the liquids are not ferroelectric[3]. It could be brought about by the combined ordering effects of the walls and the intermolecular forces characteristic of nematic liquids.

Secondary Electron Emission of Evaporated Titanium Films

The secondary electron emission coefficient δ of evaporated titanium films has been measured at target voltages between 0 and 1,875 V with electron current densities ranging between 2 and 50 μamp/cm². The bias voltage applied to the secondary electron collector was between 0 and +12 V. The experiments were done in an ultra-high vacuum system made of stainless steel, sealed with aluminium wire gaskets, and pumped by a fractionating oil diffusion pump. The diffusion pump was fitted with a liquid nitrogen trap and charged with silicone 704 fluid[1].

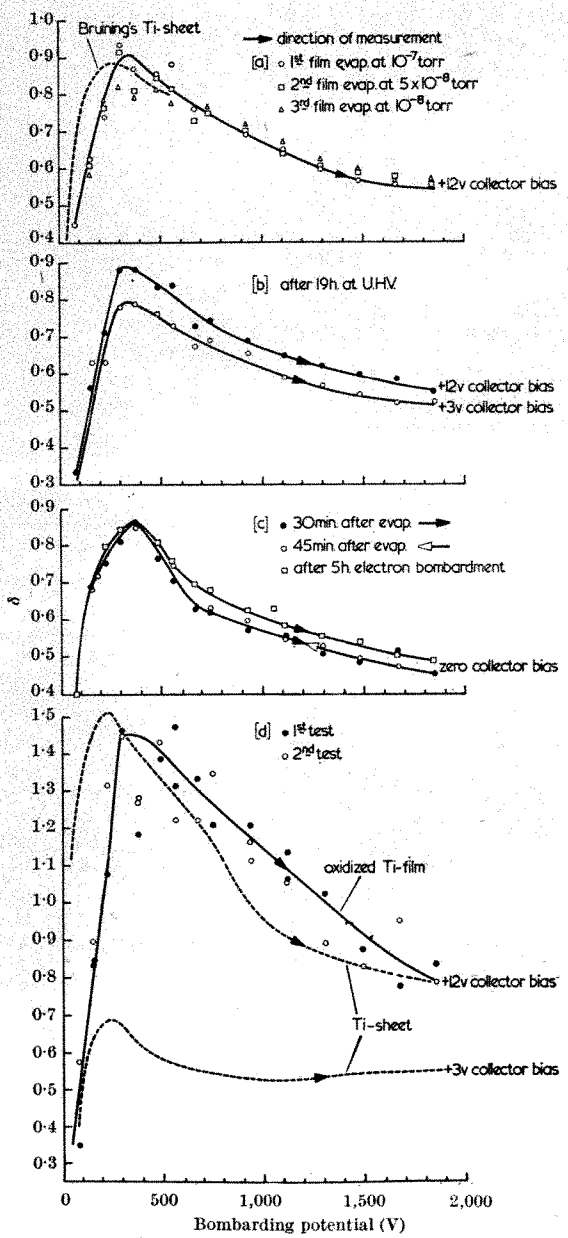

Fig. 1

Tests were made to ensure that the target would remain free of adsorbed oil molecules during the measurement of δ. The target was bombarded with electrons and the rate of growth on its surface of polymerized organic matter measured. Under ultra-high vacuum conditions (ultimate pressure 10^{-9} torr) the growth-rate of the organic deposit was < 5 Å/h (ref. 2); the period for measuring a δ/voltage curve was about 15 min.

Values of δ measured at a pressure of 8×10^{-10} torr are given in Fig. 1*a* for three titanium films deposited in sequence on to a glass substrate; each film was about 200 Å thick. Although the evaporant was thermally degassed during system bake-out the pressure still rose during evaporation, but the pressure rise was less on each successive evaporation. During the third evaporation the pressure rose to only 10^{-8} torr and fell to $< 8 \times 10^{-10}$ torr after the evaporation.

Values have been reported by Bruining[3] of δ for titanium sheet heated in vacuum to dissolve the surface oxide in the bulk metal and his results are shown in the dotted curve in Fig. 1*a*.

The secondary emission of the third titanium film was remeasured after 19 h in ultra-high vacuum (5×10^{-10} torr) and was found to be unchanged (Fig. 1*b*). Likewise continuously bombarding a thick titanium deposit (500 Å) with 30 μamp/cm² for 5 h under the same vacuum conditions caused only a small change in the δ/voltage curve (Fig. 1*c*).

A titanium film evaporated in ultra-high vacuum was oxidized by raising the pressure in the vacuum vessel with dry air to 0·1 torr for 24 h and the δ/voltage curve measured (Fig. 1*d*). The δ/voltage curve differed from that of the unoxidized metal and resembled the curve for oxidized titanium sheet as shown in the dotted curves (Fig. 1*d*). The target voltage for δ maximum of titanium sheet is lower than that for the oxidized titanium film. The rough surface of the oxidized titanium sheet prevents the primary electrons from striking the surface at normal incidence and it is known that varying the incident angle lowers the voltage at which δ maximum occurs.

GEOLOGY

Potassium–Argon Age Determinations on Some Rocks from the Broken Hill Region of New South Wales

Age measurements have been made on a number of rocks from Broken Hill in Australia. The significance of these will be discussed in a forthcoming publication[1]. The following is a brief description of their geological settings together with those age measurements which were made using the isotope dilution technique of potassium–argon age determination.

The Precambrian rocks of the Willyama complex have been subjected to a series of metamorphic and intrusive episodes. A general outline of these events is as follows.

Metamorphism M1. Throughout most of the Willyama province the original rocks, which were largely detrital sediments, have been reconstituted into garnetiferous, feldspathic, siliceous and pyroxenic gneisses.

Retrograde metamorphism has occurred subsequent to *M1* (refs. 2–5).

Metamorphism M2. Pelitic rocks of the north-western Barrier Ranges are dominantly coarse-grained mica schists exhibiting evidence of further, mainly metasomatic metamorphism. They can be distinguished under the microscope from the products of *M1* by their textures.

Metamorphism M3. Pelitic rocks occupying a belt extending northwards from Lake's Grave along the line of the Mount Franks fault have been recrystallized to knotted quartz-mica schists bearing porphyroblasts of andalusite. Basic rocks have been recrystallized to coarse-grained amphibolites. Metamorphism *M3* was a period of strong deformation and extends in part into the zone occupied by *M2* rocks. Metamorphisms *M2* and *M3* may be related.

Metamorphism M4. Muscovite schists of the *M2* type in places have been modified to fine-grained chlorite–sericite schists, usually found in shear zones parallel to the *M1–M2* schistosity. The intensity of this dynamic metamorphism increases towards the Torrowangee unconformity and it is possible that *M4* is related to the folding and metamorphism of the Torrowangee rocks above the unconformity.

Mundi Mundi Granite. Two large bodies of this massive muscovite–microcline–oligoclase granite outcrop immediately to the east of the *M3* zone of knotted schist. Lack of foliation suggests a late stage of intrusion though its relationship to the knotted schists is not yet clear. Outcrops of the granite are mainly restricted to the *M2* zone.

Boulders of granite and of *M3* type schists have been reported in the basal tillites of the Torrowangee Series[6]. Hence both pre-date the deposition of these Proterozoic rocks.

Shattering and shearing[3,7] of the granite were probably caused by metamorphism *M4* during the folding of the Torrowangee rocks.

In an attempt to clarify the geological history of the region a large number of potassium/argon age measurements were made using both the total volume and isotope dilution techniques. In view of the possible unreliability of the former only the results yielded by the latter will be considered in this work. The samples used are listed here and the results given in Table 1.

Table 1. Results of Potassium/Argon Age Determinations

Specimen	Mineral	K_2O (%)	Atmospheric contam. (%)	Vol. of radiogenic ^{40}Ar (mm^3) N.T.P./g of sample	Apparent age and error m. yr.
84336	Hornblende	0·70	0·60	0·0300	987 ± 62
84332	Hornblende	0·45	0·8	0·0170	894 ± 57
84368	Muscovite	3·53	0·4	0·2017	1,226 ± 54
84367	Biotite	5·26	4·8	0·1633	762 ± 38
	Muscovite (*a*)	7·19	2·4	0·4138	1,233 ± 54
	Muscovite (*b*)	6·97	1·1	0·4526	1,345 ± 30
84359	Muscovite (i)	6·47	1·8	0·2440	892 ± 43
	Muscovite (ii)	6·47	0·3	0·2604	939 ± 22
84365	Muscovite	9·90	0·4	0·6173	1,307 ± 56
84391	Muscovite	9·61	0·6	0·4113	985 ± 38

$\lambda_e = 0{\cdot}584 \times 10^{-10}\ yr^{-1}$ $\lambda_\beta = 4{\cdot}72 \times 10^{-10}\ yr^{-1}$

Small Roman numerals denote repeated determinations on same mineral concentrate.
Small letters denote determinations performed on different mineral concentrates from same rock.

Attempts to date metamorphism M1. Mineral concentrates prepared from high-grade gneisses and amphibolites, products of first regional metamorphism showing little effects of subsequent metamorphisms (hornblendes 84336 and 84332).

Attempts to date metamorphism M2. Specimen 84368 from west of the Mt. Robe Mine containing biotite, undergoing shredding and reaction to sillimanite, being enclosed with its reaction products in large crystals of muscovite.

Attempts to date metamorphism M3. Specimen 84367, from the Silver King Mine, contained perfectly fresh andalusite porphyroblasts in a biotite–muscovite–quartz schist. Both micas were measured.

Attempts to date the folding and metamorphism of the Torrowangee Series (M4 ?). Concentrated muscovite was prepared from a fine-grained schist (specimen 84359) occurring within tillites near the unconformity at Cartwright's Creek.

Attempts to date the consolidation of the Mundi Mundi granite. Muscovite was separated from specimens 84365 from the large mass east of Mt. Robe, and 84391 from the type locality at Mundi Mundi Creek.

From the results listed in Table 1 it is clear that the influence of the final Torrowangee movements was widespread and that these movements took place about 916 million years ago. This compares well with the lead isotope age determinations on ore bodies of the 'Thackaringa type' ('younger than 1,000 million years'[8]).

Data from the Mundi Mundi Granite would suggest that it has an age of some 1,307 million years and was affected in part by the *M4* movements.

The apparent ages yielded by muscovites from samples 84368 and 84367 must be considered to be minimum values and not to date metamorphisms *M2* and *M3* with precision. They do, however, suggest a close relationship in time between *M2* and *M3* and the emplacement of the granite.

Metamorphism *M1* cannot be dated accurately with the information yielded by this investigation, though on geological evidence it must be older than 1,345 million years. Russell and Farquar[9] using the lead isotope method have, however, assigned an age of 1,600 million years to the Broken Hill ore body, which is considered to be either contemporaneous with[7] or post main phase[10] of the *M1* metamorphism.

The general conclusions are as follows:

Geochronological sequence in the Broken Hill District

Geological event	Approximate age
Metamorphism *M1*	1,600 m. yr. or older
Metamorphisms *M2* and *M3*	1,345 m. yr.
Closely followed by intrusion of Mundi Mundi Granite	1,307 m. yr.
Metamorphism and folding of Torrowangee *M4*	916 m. yr.

The Cambrian metamorphic episode in Willyama rocks dated at about 520 million years and reported by Evernden and Richards[11] was not detected in the present investigation.

RADIOCHEMISTRY

Rapid Non-destructive Analysis of Chlorine by Neutron Activation

It is known that 1·0-sec chlorine-38*m* is formed by neutron irradiation of natural chlorine and that it emits 0·66-MeV γ-ray. So it seems that chlorine can be determined by short-time irradiation with neutrons followed by γ-ray spectrometry. Since the half-life appeared to be too short to bring about precise determinations, we tried at first to observe the precision of the use of ten samples of ammonium chloride, 150 mg each.

They were placed by turns in the nuclear reactor *JRR*-1 for 2·5 sec to be irradiated with neutrons at a flux of 3×10^{11} neutrons/cm²/sec, cooled for 5 sec, and counted for 1 sec. The counter used was a 2-in. thick, well-type sodium iodide crystal attached to a 256-channel pulse-height analyser. During the counting operation the sample was placed 1 cm above the crystal together with its containers made of polyethylene (inner capsule) and of polyester (outer capsule 'rabbit'). A 2,150-mg/cm² thick aluminium disk was used as an absorber for β-rays from the sample.

On the spectrum obtained the height and the 'width at half-maximum' of 0·66-MeV photopeak were measured, from which peak area was estimated by use of a formula presented by Connally and Leboeuf[1].

Thus, the coefficient of variation of single analyses (or relative standard deviation) was estimated at 14 per cent. Though the coefficient is rather large, it may still be sufficient for the purpose of rapid, non-destructive analysis for chlorine.

Then this method was modified to determine the half-life of chlorine-38*m* so as to confirm the identification of chlorine, and was applied to samples of bleaching-powder. Ammonium chloride was used as a chlorine standard. The results of the analyses are given in Table 1, and a typical spectrogram in Fig. 1.

Table 1. Results of Analyses of Bleaching Powder

Sample		Sample weight used (mg)	Chlorine found (%)
A	No. 1	393·1	30·1
	No. 2	429·2	31·9
B	No. 1	229·1	27·0
	No. 2	218·8	29·7

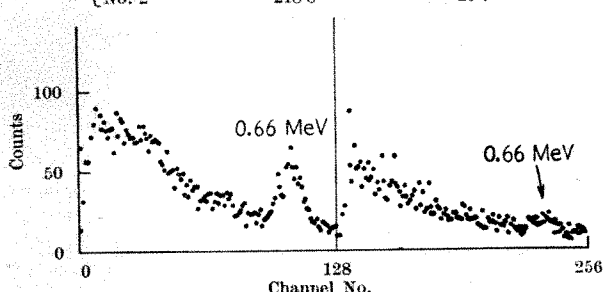

Fig. 1. γ-Ray spectrogram. Sample: 393·1 mg of bleaching powder (sample *A*, No. 1 in Table 1). Time of irradiation, transfer, first counting, interval, and of second counting are 2·5 sec, 5 sec, 1 sec, 1 sec, and 1 sec, respectively

It is deduced that the method is favourably applicable to various organic compounds in spite of the relatively low activation-cross-section of chlorine.

It was found that both sodium chloride and potassium chloride can be used as a chlorine standard.

We thank Prof. Shoji Makishima, Dr. Fumio Aoki and Dr. Toshio Nakai for helpful suggestions, and Mr. Shigeru Yamagishi for helpful assistance.

CHEMISTRY

Nature and Reactions of the Reducing Species in Aqueous Solutions irradiated with γ-rays in the Presence of Oxygen

We have previously[1] demonstrated the existence of a dehydrogenating species in de-aerated neutral aqueous solutions of aliphatic alcohols, when these are irradiated with γ-rays. This particular species, produced in a yield of $G = 0{\cdot}5$–$0{\cdot}6$ (molecules/100 eV), was assumed to be a hydrogen atom, possibly formed from excited water molecules according to: $H_2O^* \rightarrow H + OH$. A similar conclusion has also been arrived at by Rabani and Stein[2,3], using 200-kV X-rays. The identity of the dehydrogenating species as a simple hydrogen atom appears to be supported by kinetic evidence[2,3] as well as by its reaction with OH^- ions[4,5]. Other authors have suggested that one may be dealing with a radical pair (H + OH) (ref. 6) or an excited water molecule reacting as such[6,7]. For this, and other, reasons we shall represent this dehydrogenating species as H^α. The major proportion of the reducing species consists of electrons, also described as negative polarons[8], and represented here as $(H_2O)^-$.

Recently, questions have arisen concerning the existence of H^α in systems containing oxygen[7,9,10]. In particular, Hummel and Allen[10], in an investigation of the yields of hydrogen on γ-irradiation of aqueous ethanol solutions containing oxygen, concluded that there was a competition between ethanol and oxygen for a reducing species, but were unable to decide whether this was $(H_2O)^-$ or a hydrogen atom. Somewhat similar effects in oxygenated lactate solutions, irradiated with 200-kV X-rays, have been observed by Johnson[11]. We have re-investigated this effect using oxygenated solutions of sodium formate. This particular organic solute was selected because: (*a*) its reaction with the negative polaron does not apparently lead to formation of hydrogen[12]; (*b*) the formate ion has a relatively high reactivity towards H^α (ref. 13) as well as to externally generated hydrogen atoms[14]. Solutions of formate of varying concentrations (10^{-3}–5×10^{-1} M) were saturated with oxygen (1 atm.) and irradiated with cobalt-60 γ-rays. The yields of hydrogen were determined mass spectrometrically, after removal of excess oxygen with yellow phosphorus, this method giving results accurate to about ±5 per cent. The results (Table 1) show that the yields of hydrogen increase with increasing formate concentration, indicating a reaction involving H^α and not $(H_2O)^-$. Furthermore, the results follow simple competition kinetics leading to a value of $G(H^\alpha) = 0{\cdot}75 \pm 0{\cdot}1$, in fairly good agreement with that obtained in de-aerated systems. Thus, both $(H_2O)^-$ and H_a can undergo reactions in the presence of oxygen, in disagreement with the statement of Hayon[7] that only $(H_2O)^-$ reacts under these conditions.

Over the range of formate concentration where $G(H_2)$ increases markedly, the yield of hydrogen peroxide changes relatively little (Table 1), a situation similar to that observed in the ethanol–oxygen system[10]. This would be expected if H^α is, in fact, a hydrogen atom, reacting competitively, according to: $H + HCOO^- \rightarrow H_2 + COO^-$ and $H + O_2 \rightarrow HO_2$, since the reaction with formate will be followed by, $COO^- + O_2 \rightarrow CO_2 + O^-$. Given the accepted mechanism for the radiolysis of aqueous oxygenated formate solutions[15] and assuming $G^w_{H_2} = 0{\cdot}39$, the value of $G(H_2)$ at the lowest formate concentrations, the results presented here lead to values of $G((H_2O)^-) = 2{\cdot}3 \pm 0{\cdot}1$ and $G(H^\alpha) = 0{\cdot}75 \pm 0{\cdot}1$. In certain other aqueous systems, for example, in solutions containing N_2O + alcohol[13], or CO_2 + alcohol[16], $G(H^\alpha)$ and $G((H_2O)^-)$ have been directly measured. The values obtained for $G(H^\alpha)$ are in agreement with that obtained here. However, values of $G((H_2O)^-)$ up to 2·9 have been observed.

Table 1. YIELDS OF HYDROGEN AND OF HYDROGEN PEROXIDE ON IRRADIATION, WITH COBALT-60 γ-RAYS, OF AQUEOUS SOLUTIONS OF SODIUM FORMATE IN THE PRESENCE OF OXYGEN (1 ATM.)

Concentration of sodium formate (mole/l.)	$G(H_2)$	$G(H_2O_2)$
10^{-3}	0·39	3·48
10^{-2}	0·39	3·58
10^{-1}	0·64	3·59
$1·5 \times 10^{-1}$	0·70	—
2×10^{-1}	0·78	—
5×10^{-1}	0·92	3·57

The conclusion that both H^{α} and $(H_2O)^-$ are present in irradiated oxygenated formate solutions is inconsistent with the findings of Czapski and Allen[9] that, in the γ-radiolysis of solutions of oxygen and hydrogen peroxide, the reducing radicals behave as if they are all $(H_2O)^-$. If the results of Czapski and Allen are accepted, then it is apparent that the reactions of H^{α} with either formate or with oxygen do not lead to hydrogen peroxide; in these circumstances, it may be necessary to consider other concepts of the identity of H^{α}. In order to settle this aspect we feel it important to have a further independent determination of the value of $G((H_2O)^-)$, in solutions irradiated in the presence of oxygen.

We thank Prof. J. J. Weiss for his interest in this work. We also thank Prof. G. Stein, Dr. G. Czapski and Dr. G. R. A. Johnson for useful discussions and to Mr. P. Kelly for mass spectrometric analysis. One of us (M. S.) is indebted to the U.S. Army for financial support.

Infra-red Spectra of some Anhydrous Complex Cyanide Acids

AN appreciable number of acids derived from metal cyanide complexes are known, and many can be obtained anhydrous. However, very little information is available as to their structures in the solid state. Penneman *et al.*[1] measured the infra-red spectrum of solid anhydrous aurocyanic acid, $HAu(CN)_2$, and reported a single cyanide stretching frequency at 2,146 cm^{-1} and an Au—C stretch at 399 cm^{-1}. They found no absorption which could be attributed to a hydrogen stretching frequency.

This communication reports the detailed infra-red spectra of this acid, cobalticyanic acid and ferrocyanic acid in the region 5,000–400 cm^{-1}. The results obtained, together with those for related compounds, are given in Table 1 and some of the spectra are reproduced in Fig. 1.

The spectrum of ferrocyanic acid differs considerably from those of the other two acids. The strong broad absorption (with some structure) in the region 3,300–2,300 cm^{-1}, and the corresponding bands at 2,460 cm^{-1}, 2,270 cm^{-1}, and 1,908 cm^{-1} in the deutero-acid can plausibly be attributed to the stretching modes of N—H (or N—D) bonds; some, at least, of the hydrogen atoms are presumably

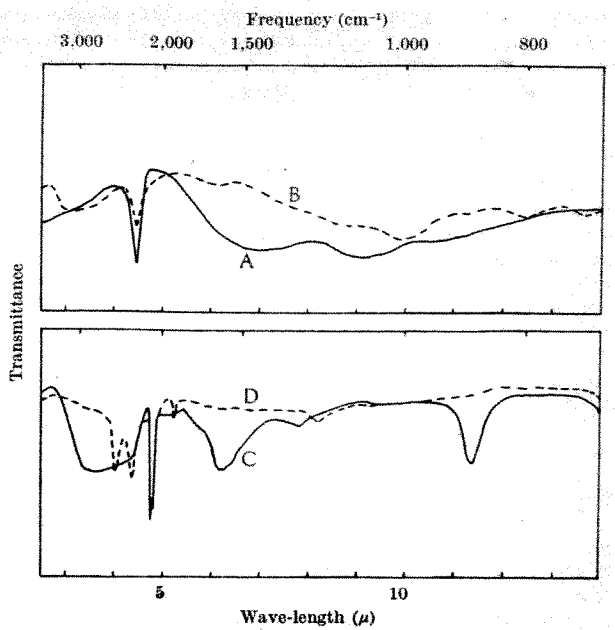

Fig. 1. Infra-red spectra of: *A*, $HAu(CN)_2$; *B*, $DAu(CN)_2$; *C*, $H_4Fe(CN)_6$; *D*, $D_4Fe(CN)_6$

Table 1
(cm^{-1})

C≡N Stretches

$K_3Co(CN)_6$, 2130*s*. $Ag_3Co(CN)_6$, 2188*s*. $(CH_3)_3Co(CN)_6$ (Hartley's (ref. 2) β-ester), 2280*s* (C≡N of C≡N—CH_3), 2154*s* ('free' C≡N). $H_3Co(CN)_6$, 2193*s*. $D_3Co(CN)_6$, 2193*s*. $K_4Fe(CN)_6$, 2140*s* (Fe—C at 580*s*). $H_4Fe(CN)_6$, 2110*s*, 2086*s*, 2028*w*. $D_4Fe(CN)_6$, 2095*s*. $KAu(CN)_2$, 2143*s*. $Au(CN)$, 2238*s*. $HAu(CN)_2$, 2212*s*. $DAu(CN)_2$, 2210*s*.

Other Bands

$H_4Fe(CN)_6$: 3300–2300*vs*, broad (N—H stretch), 1800–1400*vs*, broad, 1270*w*, 875*s* (N—H deformation), 686*w*, 659*w*, 580*s* (Fe—C stretch).
$D_4Fe(CN)_6$: 2460*s*, 2270*s*, 1908*w* (N—D stretches), 1209*m*, 1015*w*, 960*w*, broad, 634*m* (N—D deformation), 580*s* (Fe—C stretch), 500*w*, 430*w*.
$HAu(CN)_2$: 4200*w*, broad, 1400*s*, broad (N—H stretch ?), 1110*s*, broad (N—H deformation ?).
$DAu(CN)_2$: 3000*m*, broad, 1010*m*, broad (N—D stretch ?), 810*m*, broad (N—D deformation ?).

moderately strongly hydrogen-bonded to adjacent —C≡N groups. The bands at 1,600 cm^{-1} and 875 cm^{-1} (which shift appropriately on deuteration) may be hydrogen deformation modes, although it is possible that the 1,600 cm^{-1} band is a strongly hydrogen-bonded N—H stretching vibration. This band could also arise from small amounts of retained water, although it may be noted that the analysis of ferrocyanic acid indicates that it is anhydrous[3] and prolonged heating *in vacuo* did not diminish the intensity of this band. Two cyanide stretching frequencies are observed with $H_4Fe(CN)_6$ while $D_4Fe(CN)_6$ gives a broad asymmetric peak with a low-frequency shoulder.

Aurocyanic acid and cobalticyanic acid, on the other hand, give single cyanide stretching frequencies. The bands, although broader than in the corresponding potassium salts, are quite symmetrical. The cyanide-stretching frequency of aurocyanic acid found in this work does not agree with the value given by Penneman *et al.*[1]; their value is almost identical with that found for $KAu(CN)_2$.

Both $HAu(CN)_2$ and $H_3Co(CN)_6$ show only slight absorption around 3,000 cm^{-1}, but give very strong general absorption with some structure below about 1,900 cm^{-1}. In aurocyanic acid the bands at 1,400 cm^{-1} and 1,110 cm^{-1} shift to lower frequencies on deuteration. This broad absorption is very similar to that found in certain acid salts such as sodium hydrogen diacetate, where symmetrical O—H—O hydrogen bonds have been postulated[4–6]. It therefore seems plausible that in aurocyanic and cobalticyanic acid there are very strong and possibly symmetrical N—H—N hydrogen bonds. This is consistent with the single cyanide stretching frequencies. From the available data it is not possible to distinguish between a truly symmetrical hydrogen bond with a single potential

minimum and a very strong but asymmetrical hydrogen bond. Although hydrogen bonds between nitrogen atoms are normally rather weak, these acids seem to provide a favourable opportunity for strong hydrogen bonding. Symmetrical-type hydrogen bonding would result in reasonable structures for both compounds, that is, infinite chains for aurocyanic acid, and a three-dimensional lattice based on linked octahedra for cobalticyanic acid. Further work is in hand and it may be noted that preliminary infra-red data on a number of related anhydrous acids indicate that they fall into two classes which resemble ferrocyanic acid or cobalticyanic and aurocyanic acids, respectively.

Measurements were made using nujol and fluorolube mulls, a Perkin–Elmer model 21 spectrometer with calcium fluoride, sodium chloride and potassium bromide prisms, and Infracord and Unicam *SP*200 spectrometers.

The acids were prepared by standard procedures[1–3] and dried *in vacuo* at 80°–100° C. The deutero acids were obtained either directly, using deuterium chloride and deuterium oxide, or by repeated exchange with deuterium oxide, and the extent of deuteration (> 90 per cent) was checked from examination of their proton resonance spectra in deuterium oxide solution.

We thank Mr. P. Nicholson for samples of $H_4Fe(CN)_6$ and the Ethyl Corporation of America for financial support to one of us (D. J.).

Far-infra-red Absorption Spectra of some Complex Halides of Molybdenum and Tungsten

In a previous publication[1] Adams and Gebbie reported the far-infra-red absorption spectra of some transition metal complex halides containing regular octahedral ions of the type MX_6^{n-}, X = halogen. We have now extended our observations to a series of halides of molybdenum and tungsten recently prepared by Edwards, Kennedy, Peacock and Said[2].

The spectra were obtained by means of a far-infra-red interferometer, the samples being in the form of 'Nujol' mulls sealed in polythene cells; details of techniques and procedure have already been published[1]. The results are given in Table 1.

Table 1. Far-Infra-red Absorption Frequencies (cm^{-1}) of Some Complex Halides of Mo^{IV} and W^{IV}

	ν_3	ν_4	Lattice mode (?)
K_2WCl_6	324	165	77
Rb_2WCl_6	306	160	66
Cs_2WCl_6	308	166	71
K_2MoCl_6	340	174	74
Rb_2MoCl_6	334	172	70
Cs_2MoCl_6	325	170	70
K_2WBr_6	229	74	—
Rb_2WBr_6	220	78	—
Cs_2WBr_6	214	60	—

Spectra of the halides $M_2'[MCl_6]$, M = molybdenum or tungsten, are analogous to those found for compounds such as K_2PtCl_6 and K_2IrCl_6, a three-band spectrum being observed[1]. The spectra of the molybdenum chlorides all had absorption near 230 cm^{-1}; but as this increased if the sample was exposed to air, we consider it to be due to a breakdown product. Weak absorption was also found in Rb_2WBr_6 and Cs_2WBr_6 at 116 and 114 cm^{-1} respectively. Absorption in the range 308–340 cm^{-1} is due to ν_3 (metal-chlorine stretching) and that at 160–174 to ν_4 (metal-chlorine bending). In the bromides, M_2WBr_6, ν_3 and ν_4 are correspondingly lower and compare closely with those observed for K_2PtBr_6, namely, 240 and 78 cm^{-1}. As expected ν_3 is lower for the tungsten than for the molybdenum compounds, and it is interesting to note that ν_4 follows this trend.

There is a marked dependence of ν_3 (and to a lesser extent, ν_4) on the nature of the cation. As the size of the cation is increased, cation–anion interactions decrease. The rise in ν_3—and hence in the M–X bond-strength—with increasing ionic interaction may be caused, at least in part, by varying amounts of $d\pi$–$d\pi$ bonding between metal and halogen in the anion. This dative π-bonding, which Woodward and Ware[3] have shown to be present in $PtCl_6^{2-}$ and $PtBr_6^{2-}$, will be favoured by the proximity of a relatively small cation such as K^+.

In $(NEt_4)W^{V}Cl_6$, ν_3 is at 329 cm^{-1} (ref. 4); in $Cs_2W^{IV}Cl_6$, ν_3 is at 308 cm^{-1} and would presumably be a little lower in $(NEt_4)_2W^{IV}Cl_6$. Thus a drop of some 25 cm^{-1} in ν_3 occurs as the oxidation state of tungsten is changed from +5 to +4, comparable with that of 37 cm^{-1} for the +4 to +3 change in K_2IrCl_6 and K_3IrCl_6 (ref. 1).

The third, and lowest, frequency band found for the chlorides (Table 1) is in addition to the predicted infra-red-active internal modes of an isolated MCl_6^{2-} ion. It was previously assigned to a lattice mode[1], largely on the basis of the large shift it suffered (45 cm^{-1}) in $M_2'IrCl_6$ when M' was changed from K^+ to $(NH_4)^+$. An alternative assignment is to ν_6 (f_{2u}), the inactive bending frequency, made active by the lower symmetry of the crystal lattice.

Polymorphism in Silicon Carbide

Silicon carbide exists in two distinct crystalline polymorphs, the cubic or β-form, and the hexagonal or α-form[1–3]. Although the crystal structure and related physical properties of the two forms of silicon carbide have been extensively investigated, the chemical relationship between the two silicon carbide polymorphs has apparently failed to receive equivalent attention. The problem was attacked by Baumann[4], who investigated both the chemistry of silicon carbide formation, and the rate of conversion of β-silicon carbide to α-silicon carbide at several temperatures. Baumann observed that although β-silicon carbide began to transform to α-silicon carbide slowly at 2,100° C, the reaction was rapid at 2,300° C.

The suggestion that the transformation from the cubic form to the hexagonal form may proceed via the vapour phase has been made by Slack[5]. Thus, if a solid-phase transition occurs at all, it must be very slow as compared with the vapour phase process. Indeed, Kistler[6] summarized the problem when he stated, "It is probable, although I believe the subject has not been sufficiently

explored, that the cubic form of SiC can be maintained at higher temperatures (> 2,000° C) without conversion as long as *recrystallization does not take place*".

It is the purpose of this communication to show that polymorphism in silicon carbide may be reasonably interpreted as proceeding through the vapour phase. No attempt is made to prove that silicon carbide transforms through a vapour phase condensation, only that such an interpretation is not unreasonable in view of the available facts.

According to Buerger[7], the barrier which opposes and thus regulates the rate of transformation in solid–solid reactions should be represented by the structural bonds which it is necessary to disturb during the transformation. In the case of reconstructive transformations, defined as the disintegration of one structure into small units followed by reconstruction of a new crystalline modification from these units, Buerger has related the barrier to the heat of vaporization of such units. Buerger's transition barrier can be reasonably represented by the activation energy for the phase transition in question. In the case of silicon carbide an activation energy for the β-silicon carbide to α-silicon carbide reaction can be calculated from the rate-temperature curves for the transformation as measured by Baumann. A comparison, then, of the calculated activation energy with the energy required to bring about disruption of the chemical bonds in the silicon carbide lattice can lead to a reasonable interpretation of the path connecting the two silicon carbide polymorphs.

In his paper, Baumann plotted two time–temperature curves for the conversion of β-silicon carbide to α-silicon carbide, from which Table 1 was deduced.

Table 1. Rate Data on the Transformation. β-Silicon Carbide to α-Silicon Carbide

Time (sec)	Temp. (° C)	β-Silicon carbide (%)	α-Silicon carbide (%)	Time (sec)	Temp. (° C)	β-Silicon carbide (%)	α-Silicon carbide (%)
0	2,100	100	0	0	2,300	100	0
300	2,100	86	14	300	2,300	16	84
600	2,100	81	19	600	2,300	5	95
900	2,100	63	37	900	2,300	1	99
1,200	2,100	67	33	1,200	2,300	0	100

It should be noted that in his time-temperature studies, Baumann used mixtures of silica and carbon rather than crystals of β-silicon carbide. In work on the formation of silicon carbide from $SiO_2 + C$ he found that β-silicon carbide began to form at 1,400°–1,500° C, and that the reaction was complete at 1,700° C. By directly observing the reaction by means of the thermal microscope Baumann found that the reaction between silica and carbon at approximately 2,200° C was quite rapid, β-silicon carbide being formed in about a minute or less. (An excellent 16-mm colour film entitled, "Exploration with the High Temperature Microscope," is available from the Carborundum Co., Niagara Falls, New York.) For purposes of this discussion, therefore, it will be assumed that in the aforementioned time–temperature curves β-silicon carbide was present at 'time-zero'.

From the results shown in Table 1 it was found that first-order plots for the conversion of cubic to hexagonal silicon carbide could be calculated. These are shown in Fig. 1.

The average rate constant for the transformation was found to be $4{\cdot}22 \times 10^{-4}$ sec^{-1} (± 20 per cent) at 2,100° C, and $5{\cdot}40 \times 10^{-3}$ sec^{-1} (± 10 per cent) at 2,300° C. From the usual plot of log k versus $1/T$ the activation energy for the transformation was found to be 158 kcal mole^{-1} (± 20 per cent).

Drowart, DeMaria and Inghram[8] have recently measured the partial pressures of various silicon–carbon species over silicon carbide in the temperature range 2,149 to 2,316° C, and have calculated the heats of formation of the various gaseous species from hexagonal silicon carbide. From the work of Drowart *et al.*, an estimate of the heat of

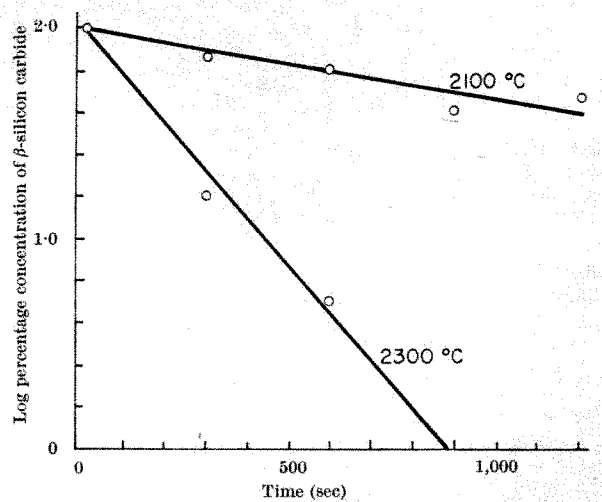

Fig. 1. First-order plot for the reaction. β-Silicon carbide → α-silicon carbide

vaporization of silicon carbide at 2,149° and at 2,316° C may be obtained by considering the partial molal equation for the total heat of reaction (ΔH) to form the various gaseous species from solid silicon carbide. The partial molal equation is[9]:

$$\Delta H = n_1 \Delta H_1 + n_2 \Delta H_2 + n_3 \Delta H_3 \qquad (1)$$

where n_1, n_2, and n_3 represent the mole fractions of the various gaseous species in equilibrium with solid SiC, and ΔH_n the corresponding heats of reaction to form the various species. The mole fractions are readily determined from Raoult's law.

From the preceding data, the total pressure over SiC was calculated to be $2{\cdot}43 \times 10^{-5}$ atm. at 2,149° C, and $2{\cdot}53 \times 10^{-4}$ atm. at 2,316° C. Carbon–silicon species with partial pressures less than $1{\cdot}0 \times 10^{-6}$ atm. were neglected. It was also assumed for purposes of this discussion that the heats of formation of gaseous species from silicon carbide are the same for both the cubic and hexagonal polymorphs. This is considered to be a valid assumption in light of recent work[10], in which it has been shown that the ΔH of formation of both cubic and hexagonal silicon carbide at 298° K is $-15{\cdot}0 \pm 2$ kcal mole^{-1}. From these data, the total heat of vaporization of the gaseous species in equilibrium with silicon carbide (solid) at both 2,316° and 2,149° C is found to be approximately 133 kcal mole^{-1}.

The estimated activation energy of 158 kcal mole^{-1} (± 20 per cent) for the β-silicon carbide to α-silicon carbide transformation as deduced from Baumann's data is not in disagreement with the value of 133 kcal mole^{-1} for the calculated heat of vaporization of gaseous species from silicon carbide. The latter value is reasonably close to the heat of formation of silicon gas since this material accounts for 86 mole per cent of the gaseous species over silicon carbide at 2,149° C, and 79 mole per cent at 2,316° C. It would appear, therefore, that it is not unrealistic to picture the conversion of β-silicon carbide to α-silicon carbide as a reconstructive transformation, proceeding through a vapour transport mechanism involving gaseous silicon, and various silicon carbide species.

The contentions of Scace and Slack[5], and of Kistler[6] appear to be very plausible, in light of the limited data which are available concerning the β→α transformation. In spite of this, however, some recent observations on the behaviour of silicon carbide at high temperatures are difficult to understand in light of Baumann's data. For example, Scace and Slack[11] have observed that cubic silicon carbide could be heated to approximately 2,830° C with no transformation taking place, and that both cubic

and hexagonal crystals of silicon carbide could be grown side-by-side from the vapour phase at 2,600° C.

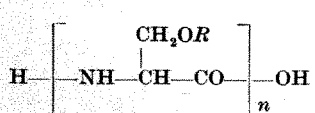
Syntheses of Poly-DL-Serine Derivatives containing Cytotoxic Groups

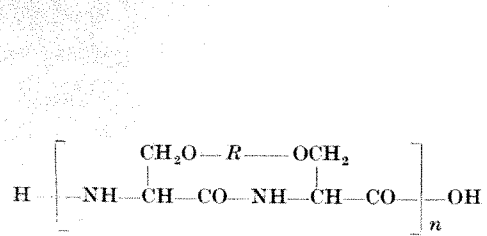


Nature has often used the trick of having a functional group carried by a larger structure of polypeptide character. This idea prompted me to use a polypeptide, namely polyserine, as carrier of groups with cytotoxicity and latent cytotoxicity.

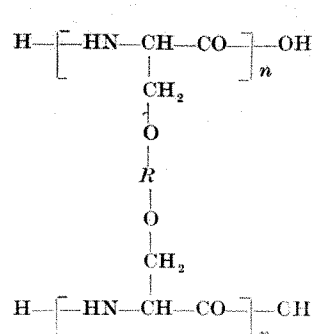
Several serine derivatives have served as anti-tumour agents[1,2], but so far as I know polyserine has not yet been tried as a carrier moiety.

Poly-DL-serine was prepared from the *O*-benzyl-DL-serine-*N*-carboxylic acid anhydride by polymerization in boiling chloroform using triethylamine as initiator[3]. The benzyl groups were removed by suspending the polymer in dioxane saturated with hydrogen bromide and allowing the mixture to stand in the cold[1].

Poly-DL-serine, purified by dialysation followed by freeze-drying, was coupled with methanesulphonyl chloride, in pyridine. According to analytical data (required, S 17·5, N 7·7; found, S 16·4, N 7·7) and infra-red spectroscopic investigations nearly all OH-groups could be blocked with the well-known cytoactive methanesulphonyl-group (I).



I succeeded in coupling polyserine in the same manner with chloromethanesulphonyl chloride[5] (required, S 14·7, Cl 16·3, N 6·4; found, S 13·8, Cl 15·5, N 6·7) (II).



I $R=SO_2CH_3$

II $R=SO_2CH_2Cl$

I then examined the possibility of attaching latent mustard groups to polyserine. For this purpose polyserine was coupled with di-(2-chloroethyl)-phosphoramidic dichloride[6] in pyridine-dioxane. The resulting polypeptide derivative is insoluble in water, in alcohol and in most organic solvents. According to analytical data (required, C 33·2, H 4·5, N 11·6, P 8·6, Cl 19·6; found, C 33·1, H 4·4, N 11·3, P 8·2, Cl 19·1) and infra-red spectroscopic investigations, phosphoric acid esters are formed with the participation of two OH-groups. The two OH-groups may belong to two neighbouring serine units, forming cyclic esters, as formulated in III, but there is also a possibility of the formation of phosphoric acid ester linkages between two polyserine chains (IV).

III IV

III, IV $R=PON(CH_2CH_2Cl)_2$

It cannot be overlooked, naturally, that on each NH_2-terminated chain end there is a possibility for the formation of cyclic phosphamide esters with the participation of the OH- and NH_2-groups of the same, terminal standing serine-unit.

Further investigation and proof of the proposed structures are in progress.

The biological tests were carried out by Dr. B. Szende and Dr. K. Németh in the I. Institute of Pathological Anatomy and Experimental Cancer Research, Medical University of Budapest. Their results will be submitted for publication elsewhere.

I thank Prof. V. Bruckner for advice and criticism. I also thank Mr. P. Sohár and Mr. F. Ruff for the infra-red spectroscopic analyses.

Use of Alkyltrimethylammonium Bromides for the Isolation of Ribo- and Deoxyribo-nucleic Acids

The use of cetyltrimethyl ammonium bromide for the isolation of nucleic acids and for the separation of RNA from DNA was first reported in 1951[1–3] and since has been used successfully for the isolation of DNA from bacteria[4]. The cetyltrimethylammonium bromide originally used was 'Cetavlon' (Imperial Chemical Industries Pharmaceuticals, Ltd.). A change in the nature of this material and modifications to the procedure used for the isolation of nucleic acids have necessitated a re-examination of the method.

Before May 1953 'Cetavlon' contained 85 per cent alkyltrimethylammonium bromides including a large proportion of the cetyl compound and some longer chain compounds. Since then a product of higher solubility, which contains a considerable proportion of the tetradecyl compound, has been issued. This change, which is advantageous from the pharmaceutical point of view, makes 'Cetavlon' less satisfactory for the separation of RNA from DNA, although it can still be used to separate nucleic acids from neutral compounds. In order to find a satisfactory alternative, a comparison has been made between 'Cetavlon', commercial cetyltrimethylammonium bromide (CTAB, British Drug Houses, Ltd.; found: C, 62·7, H, 11·9; N, 3·6; calc. for

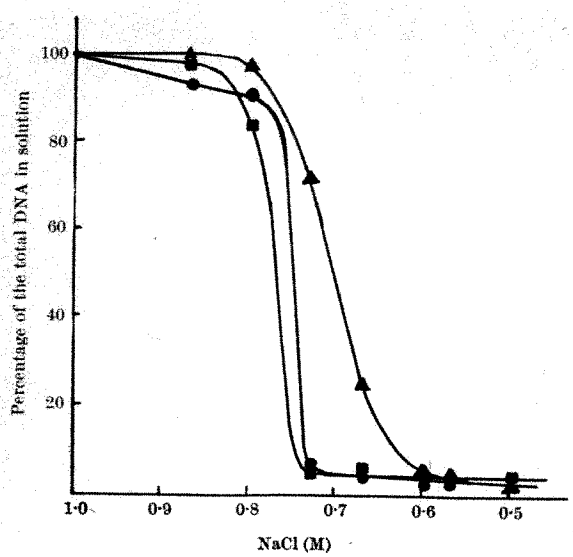

Fig. 1. Solubility of alkyltrimethylammonium salts of calf thymus DNA in sodium chloride solution at 20°. DNA concentration, 1·67 mg/ml. Concentration of alkyltrimethylammonium bromide, 6·67 mg/ml. ●, Pure synthetic cetyltrimethylammonium bromide; ■, commercial cetyltrimethylammonium bromide; ▲, 'Cetavlon'

$C_{19}H_{42}NBr$; C, 62·9; H, 11·6; N, 3·86 per cent) and a pure sample of cetyltrimethylammonium bromide (found: C, 62·9; H, 11·1; N, 3·84 per cent) which had been synthesized from cetyl alcohol, which had been found by gas phase chromatography to be 99 per cent pure (kindly supplied and analysed by Imperial Chemical Industries Dyestuffs Division, Manchester).

The solubilities of the deoxyribonucleates (from calf thymus DNA) of these alkyltrimethyl ammonium compounds are shown in Fig. 1. These show that the solubility of the deoxyribonucleate of the commercial CTAB decreased more rapidly with decreasing salt concentration than does that of the deoxyribonucleate of 'Cetavlon'. This indicates that the former should be more satisfactory for the purification of DNA. There did not appear to be any advantage in using the pure synthetic CTAB, and when this and the commercial CTAB were used to purify a sample of *Mycobacterium phlei* DNA which contained 17 per cent RNA (probably *s*RNA), in both cases samples of DNA were obtained which contained 1–2 per cent RNA.

The more recent methods for the isolation of nucleic acids, particularly the phenol method[5], give RNA of high molecular weight (microsomal RNA). This type of RNA was almost certainly lost in some previous methods, either by enzymatic degradation or by precipitation in 1 M sodium chloride and adsorption on the chloroform–protein gels formed during the deproteinization stages[6]. As this RNA is insoluble in 1 M sodium chloride its presence complicates the separation of RNA from DNA by the use of CTAB, but the microsomal RNA can be readily removed from the DNA by precipitation with 1 M sodium chloride before separating the DNA from the *s*RNA by means of CTAB. A typical procedure for the isolation of the nucleic acids from the aqueous layer of a phenol-*p*-aminosalicylate extraction[5] of a micro-organism is as follows:

The aqueous layer is poured into ethanol (3 vol.) and the precipitate removed and dissolved in water. The solution is made 1 molar with respect to sodium chloride and kept at 0° for 18 h. The precipitate of microsomal RNA is centrifuged off, dissolved in water and reprecipitated with M sodium chloride. It is finally dissolved in water, dialysed and freeze-dried. The supernatant liquid is brought to 20° and an aqueous solution of CTAB (3 per cent w/v) added until the sodium chloride concentration is reduced to 0·3 M. The resulting precipitate is centrifuged off and redissolved in 1 M sodium chloride so that the nucleic acid concentration is approximately 3 mg/ml. An aqueous solution of CTAB (2 per cent w/v) is then added (at 20°) until the sodium chloride concentration is 0·55–0·60 M (the exact concentration varies with the source of the DNA and the degree of polymerization; highly polymerized calf thymus DNA separates at a higher salt concentration) and the resulting precipitate of DNA (CTAB salt) centrifuged off. This can be purified by redissolving in 1 M sodium chloride and reprecipitating. The CTAB salt of DNA is converted to the sodium salt by dissolving the former in 1 M sodium chloride and precipitating the sodium salt with ethanol (3 vol.). Dialysis and freeze-drying give DNA, which contains 1–3 per cent RNA. The low molecular weight RNA (containing *s*RNA) is isolated from the supernatant obtained after precipitation of the DNA with ethanol. This precipitate is dissolved in water, dialysed and freeze-dried.

The foregoing method has been used to isolate DNA from *Aspergillus niger*, *Tetrahymena pyriformis*, *Polytomella papillata*[7], *Serratia marcescens*[8], and *Mycoplasma mycoides*, var. *capri*[9]. Precipitation with CTAB effectively separates the nucleic acids from neutral polysaccharides. Acidic polysaccharides are precipitated by CTAB, but most are redissolved in 0·3 M sodium chloride[2]. Some acidic polysaccharides and acidic cell wall material may contaminate the nucleic acids, however, and have to be separated by other means[8]. When the method is used in conjunction with phenol extraction, protein contamination is usually very slight, but any traces which remain can be removed by shaking the solution of nucleic acid in 1 M sodium chloride with chloroform and amyl alcohol[6].

The use of CTAB for the isolation of nucleic acids has several advantages. It is available cheaply in large quantities, the precipitates formed with nucleic acids are easy to separate, and the sodium nucleates can be easily recovered either by ethanol precipitation as described here, or by extraction of a solution of the CTAB salt in 1 M sodium chloride with chloroform. Also DNA can be readily separated from RNA without the use of enzymes. It has been shown[10] that long-chain quaternary ammonium compounds do not affect the biological activity of *s*RNA. A few batches of commercial CTAB have been found to be atypical. It is advisable, therefore, to test each batch with calf thymus DNA (Fig. 1).

For the biological testing of nucleic acids it is important that all the alkyltrimethylammonium compounds should have been removed. Their presence may be detected by the use of solochrome green *V*150 (Imperial Chemical Industries Dyestuffs Division, Manchester). Addition of an aqueous solution (0·05 per cent w/v) of this dye (pink, λ_{max} 500 mμ) to a solution of CTAB or 'Cetavlon' gives an intense purple colour (λ_{max} 550 mμ). An accurate estimate of the amount present could not be obtained because a standard curve of CTAB with the dye was not exactly reproducible and did not obey Beer's Law at concentrations of CTAB greater than 20 μg/ml. This appeared to be due to the formation of a precipitate of CTAB with the dye at certain concentrations. However, a semiquantitative estimate of the amount present could be made by adding 0·03 ml. of a 0·05 per cent aqueous solution of solochrome green *V*150 to 0·5 ml. of the solution containing CTAB. The presence of 10 μg/ml. of CTAB could be detected visually, the optical density at 550 mμ being 0·1. Normal constituents of aqueous extracts of biological materials, namely, proteins, polysaccharides and nucleic acids, did not interfere with the reaction, but high concentrations of organic solvents such as ethanol, acetone and dioxan also gave a purple colour. A 0·05 per cent aqueous solution of solochrome green *V*150 was also useful as a spray for the detection of CTAB and similar compounds on paper chromatograms.

I thank Prof. M. Stacey for his interest in this work, Mr. C. G. James for experimental assistance and the British Empire Cancer Campaign (Birmingham Branch) for part of the expenses. Thanks are also due to Imperial Chemical Industries (Pharmaceuticals Division) and

British Drug Houses, Ltd., for information about their products.

BIOCHEMISTRY

Isolation of Two Serologically Active Trisaccharides from Human Blood-group B Substance

A previous communication[1] reported the isolation of a B-active disaccharide, identified as 3-*O*-α-D-galactopyranosyl-D-galactose, from the products of partial acid-hydrolysis of a human blood-group B specific mucopolysaccharide. This sugar was the only disaccharide detected that showed B-activity, and its absence from the hydrolysis products of human blood-group A specific substance[2,3], together with other evidence, led us to infer that this disaccharide is the terminal non-reducing unit of the blood-group B determinant structure in the original mucopolysaccharide. However, the capacity of the disaccharide to inhibit the agglutination of B erythrocytes by a human anti-B serum, although much greater than that of any simple sugar previously examined, was nevertheless much lower than that of the intact B-active mucopolysaccharide in the same system, thus supporting the idea[1,4] that the complete B-determinant structure is larger than a disaccharide unit. To investigate this possibility, the trisaccharide components in the hydrolysis products were examined, and the isolation and identification of two B-active trisaccharides are now described.

A preparation of blood-group B-specific mucopolysaccharide (3·6 g) was partially hydrolysed, and the hydrolysate was adsorbed on a charcoal–'Celite' column, as described earlier[1]. After displacement of the monosaccharides and disaccharides from the column by successive elution with water, 1·5, 2·5 and 5 per cent (v/v) aqueous ethanol respectively, further elution with aqueous ethanol (7·5 per cent v/v, followed by 10 per cent v/v) displaced a mixture (about 120 mg) of trisaccharides. Fractionation of this mixture by preparative paper chromatography, using Whatman No. 3*MM* paper and ethyl acetate–pyridine–water (10 : 4 : 3 v/v) as the irrigant, afforded 35 mg of a fraction showing B-activity. This fraction proved to be a mixture of two components (I and II) having closely similar chromatographic mobilities ($R_{lactose} = 0{\cdot}87$ and 0·92 respectively). A solution of the mixture in anhydrous methanol deposited crystals of pure component I (about 20 mg), and component II (about 10 mg; 80 per cent pure) was recovered from the supernatant solution.

Chromatography of acid-hydrolysates of I and II indicated that galactose and glucosamine were present, and analysis by the phenol–sulphuric acid[5] and Elson–Morgan[6] methods, the latter after acid hydrolysis, showed that these monosaccharides occurred, respectively, in a molar ratio of approximately 2 : 1. However, when I and II were first reduced with sodium borohydride[7] and then analysed, it was found that the galactose content was essentially unchanged, whereas the hexosamine content was negligible.

Trisaccharide I had m.p. 235°–240° (decomp.) and $[\alpha]_D^{22} = +99°$ (equil.; $c = 1{\cdot}0$ in water). Under the conditions described by Aminoff, Morgan and Watkins[8], the substance gave a negative indirect Ehrlich reaction, indicating[9] that the reducing terminal *N*-acetyl-D-glucosamine (2-acetamido-2-deoxy-D-glucose) residue was substituted at position 4. On partial acid-hydrolysis (0·02 N polystyrenesulphonic acid[10] at 80° for 4 h), the trisaccharide yielded, in addition to D-galactose and *N*-acetyl-D-glucosamine, two disaccharides which were chromatographically indistinguishable from 3-*O*-α-D-galactopyranosyl-D-galactose[1,11] and 4-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine[12] respectively. However, when the glycitol of the trisaccharide, obtained by borohydride reduction, was partially hydrolysed in the same way, the only reducing sugars detectable by chromatography among the products were galactose and 3-*O*-α-D-galactopyranosyl-D-galactose.

Periodate oxidation of trisaccharide I (4·1 mg) in 0·01 M sodium metaperiodate (10 ml.) at 22° gave rise to an initial rapid uptake of 2·1 moles/mole of oxidant, with the liberation of 0·97 mole/mole of formic acid and 0·27 mole/mole of formaldehyde. Oxidation under the same conditions after borohydride reduction[13] led to the consumption of 2·9 moles/mole of periodate and the release of 1·0 mole/mole of formaldehyde; there was no over-oxidation. Trisaccharide I is therefore believed to be *O*-α-D-galactopyranosyl-(1→3)-*O*-β-D-galactopyranosyl-(1→4)-*N*-acetyl-D glucosamine.

A syrup containing at least 80 per cent of trisaccharide II had $[\alpha]_D^{22} = +92°$ ($c = 0{\cdot}5$ in water). It gave a strong indirect Ehrlich reaction[8], and the molar extinction was about 50 per cent higher than that given by *N*-acetyl-D-glucosamine, indicating[9] that the reducing *N*-acetyl-D-glucosamine residue was substituted at position 3. When partially hydrolysed with acid in the same way as trisaccharide I, it yielded, in addition to its constituent monosaccharides, two disaccharides which were chromatographically indistinguishable from 3-*O*-α-D-galactopyranosyl-D-galactose[1,11] and 3-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine[14] respectively. Partial acid hydrolysis of the derived glycitol yielded D-galactose and 3-*O*-α-D-galactopyranosyl-D-galactose as the only reducing sugars.

When heated in 0·1 N aqueous pyridine at 65° (ref. 15), trisaccharide II was rapidly degraded, to yield free chromogen and a disaccharide which was chromatographically indistinguishable from 3-*O*-α-D-galactopyranosyl-D-galactose. On periodate oxidation, the behaviour of trisaccharide II was very similar to that of trisaccharide I, but after borohydride reduction[13], it consumed 3·8 moles/mole of periodate, and liberated 1·04 moles/mole of formaldehyde. Trisaccharide II is therefore considered to be *O*-α-D-galactopyranosyl-(1→3)-*O*-β-D-galactopyranosyl-(1→3)-*N*-acetyl-D-glucosamine.

Table 1. Oligosaccharides inhibiting the Agglutination of Human B Cells by Human Anti-B Serum

	Inhibiting substance*	Minimum amount giving complete inhibition: End-point†	: μmoles/ml.
1	Human B substance	512,000	$6{\cdot}5 \times 10^{-6}$‡
2	3-*O*-α-D-Galactosyl-D-galactose	800	4
3	3-*O*-β-D-Galactosyl-*N*-acetyl-D-glucosamine	< 50	> 100
4	4-*O*-β-D-Galactosyl-*N*-acetyl-D-glucosamine	< 50	> 100
5	3-*O*-β-D-Galactosyl-*N*-acetyl-D-galactosamine	< 50	> 100
6	3-*O*-β-*N*-Acetyl-D-glucosaminoyl-D-galactose	< 50	> 100
7	*O*-α-D-Galactosyl-(1 → 3)-*O*-β-D-galactosyl-(1 → 4)-*N*-acetyl-D-glucosamine	800	2·5
8	*O*-α-D-Galactosyl-(1 → 3)-*O*-β-D-galactosyl-(1 → 3)-*N*-acetyl-D-glucosamine	400	5
9	*O*-α-D-Galactosyl-(1 → 3)-*O*-α-D-galactosyl-(1 → 3)-D-galactose	400	5
10	6-*O*-α-D-Galactosyl-D-glucose (melibiose)	50	59
11	Methyl-α-D-galactoside	< 50	> 100
12	D-Galactose	< 50	> 111

* All non-reducing sugar residues are in the pyranose form.
† Expressed as the reciprocal of the dilution of inhibitor.
‡ Based on a molecular weight of 300,000.

The capacity of trisaccharides I and II (Nos. 7 and 8, Table 1) to inhibit the agglutination of group B cells by a human anti-B serum was compared with the activity of the five disaccharides isolated from human B substance[3] (Nos. 2–6, Table 1) and other galactose-containing compounds. The results showed that, on a molar basis, trisaccharide I (No. 7) was twice as active as an inhibitor as the active disaccharide 3-*O*-α-D-galactosyl-D-galactose[1] (No. 2), whereas trisaccharide II (No. 8) had approximately the same activity as the disaccharide and was not more active than the galactotriose (No. 9) isolated from λ-carrageenin[11]. The difference between the activities of the two trisaccharides from B substance is slight, and trisaccharide II has not yet been obtained in crystalline form, but the results may indicate that the *N*-acetyl-D-glucosamine residue makes a greater contribution to the total activity when joined through a 1→4 rather than through a 1→3 linkage. The small increase in activity between the active disaccharide and the most active trisaccharide suggests that the fourth sugar residue from the non-reducing end of the chain, and other residues still more remote from it, probably contribute little to the total activity. The degree of inhibition given by these oligosaccharide fragments is, however, very small compared with the inhibition given by the intact B substance and it is possible, as suggested earlier[1,4], that sugars attached as branching units to the fragments already isolated may make a significant contribution to the full specificity of the B determinant structure.

Immunoelectrophoresis of Sweat Proteins

The presence of mucoproteins in human sweat has already been described by one of us (M. J.)[1]; mucoproteins were also found in the sweat of the horse, the chief protein of which is albumin (the sweat glands in the horse are of an apocrine type)[2,3]. We have now examined the immunochemical behaviour of proteins in human sweat, according to their specific antigenic properties.

Using a double-diffusion technique in gel of Ouchterlony[4], four precipitation lines were found when natural sweat was tested against a rabbit immune serum against sweat proteins (obtained by immunizing a rabbit with protein, which had been isolated from a greater quantity of collected thermal sweat, of a number of normal adults); when normal human serum was tested against the rabbit immune serum against sweat proteins, two precipitation lines were found. According to Ouchterlony's reaction types[4], two of these four protein components in sweat prove to be identical with those present in normal serum, whereas the other two do not.

Using an immunoelectrophoresis microtechnique[5], five precipitation lines were obtained when the immunoelectrophoretic pattern of sweat was tested with a corresponding rabbit immune serum against sweat proteins (Fig. 1).

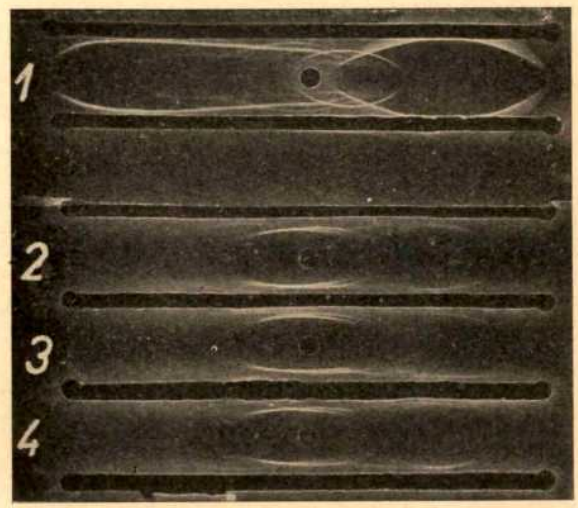

Fig. 1. Immunoelectrophoretic patterns of human sweat in comparison with human serum. 1, Normal human serum (in longitudinal basins a rabbit immune serum against human serum); 2, 3, 4, concentrated human sweat (in longitudinal basins a rabbit immune serum against sweat proteins)

At present we are trying to identify the protein components in human sweat and especially their nature as a specific product of the active secretive function of sweat gland cells.

We thank Dr. V. Křížek of the Research Institute of Balneology and Climatology, Mariánské Lázně, for collecting the sweat.

2,6,10,14-Tetramethylpentadecane (Pristane) from Wool Wax

The saturated polyisoprenoid hydrocarbon, 2,6,10,14-tetramethylpentadecane (pristane), has previously been shown to be a constituent of the liver oil of the basking shark (*Selache maxima* Gunnerus)[1,2] and a probable constituent of several other elasmobranch fish oils[3], sperm-whale liver[4] and ambergris[5]. It has more recently been identified in a distillate from petroleum crude oils[6].

We have now identified this compound as a constituent of wool wax. The hydrocarbon fraction was obtained, to the extent of 0·55 per cent, from a sample of the crude wool wax (the wool wax was generously provided by Mr. Clyde Rowntree, Wellman Combing Co., Johnsonville, S.C.) by alumina chromatography of the hexane-soluble materials. The normal and less highly branched components were removed by urea complex formation in *n*-propyl alcohol and the more highly branched components were

separated by gas-liquid chromatography utilizing a 'MicroTek 2500-*R*' instrument with dual columns and flame detection (MicroTek Instruments Inc., Oak Villa Boulevard, Baton Rouge, La., U.S.A.). Copper columns, 3/16 in. internal diameter by 6 ft. packed with 80–100 mesh 'Gas Chrom *P*' coated with 6 per cent silicone rubber *SE*–30 (Applied Science Laboratories, Inc., State College, Penn.), were used for the separation. The temperature of the columns was maintained at 130° C, and a helium flow rate of 70 ml. per min was utilized. Under these conditions pristane was eluted after 10·4 min.

Collection of the pristane eluate was accomplished with a differential temperature trap described by Stevens and Mold[7]. After rechromatographing under similar conditions, the column 'throw' was removed from the sample by chromatography in cyclopentane on alumina.

The infra-red spectrum for this purified sample was identical to that for an authentic sample of 2,6,10,14-tetramethylpentadecane and was in complete agreement with published spectra for this compound[8,6]. The gas-liquid chromatographic retention time for the isolated compound was also identical to that observed for the authentic pristane and approximated that for a normal hydrocarbon of two less carbon atoms.

Conclusive evidence for the molecular weight and structure was provided by a comparison of the mass spectrum for the compound isolated from wool wax with the spectrum for the authentic pristane. In addition to the molecular ion peak at m/e 268, major intensities were noted for ions of m/e 112, 113 and 183, in agreement with the mass spectrum published by Bendoraitis[6].

It is estimated that pristane constitutes about 1·1 per cent of the total paraffin fraction of crude wool wax. This is the first report of this compound from a non-marine source.

A Crystalline Fragment from Human Gamma-globulin

PAPAIN hydrolysis of rabbit γ-globulin has yielded a crystallizable polypeptide fragment with a molecular weight of approximately 80,000 which has no antibody activity[1]. Although analogous fragments have been crystallized from purified human myeloma globulins[2], crystallization of a similar fragment from normal human γ-globulin thus far has not been reported. By performing the papain hydrolysis in relatively concentrated solutions of human γ-globulin, however, a crystalline polypeptide fragment has been obtained. Some work on this γ-globulin fragment is reported here.

7*S* γ_2-globulin (lot 337–1, Squibb) was dialysed as a 16 g per cent solution against distilled water. Part of the dialysed solution was lyophilized and then reconstituted to a concentration of 30 g per cent in 0·1 M potassium chloride containing 0·01 M cystein hydrochloride and 0·002 M sodium ethylenediamine tetraacetate. Twice-crystallized papain was added to either the 16 g per cent or 30 g per cent solutions of γ-globulin in an enzyme to protein weight ratio of 1: 1,000 and the γ-globulin hydrolysed for 30 min in the *p*H stat at *p*H 7·0 and 5 (ref. 3); at the end of this time, 4 μmoles of sodium hydroxide had been added per μmole of protein. The hydrolysate was then dialysed at 4° C for 48 h against several changes of distilled water at *p*H 5·5; during dialysis, crystals appeared.

The crystals were redissolved easily at a *p*H of 8·0 and crystallization was effectively achieved by dialysis at *p*H 5·5. Typical crystals are shown in Figs. 1 and 2. The crystals appeared to be monoclinic with the fast optical axis parallel to the long axis of the crystal.

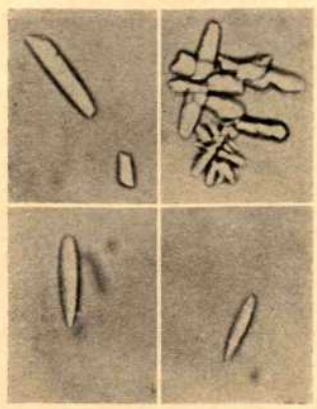

Fig. 1. Examples of crystals from first crystallization. (× *c.* 490)

Crystallized three times, the fragment had a sedimentation coefficient, $S_{w,20}$, of 3·4 *S* in a 0·6 g per cent solution, uncorrected for protein concentration and assuming a specific molal volume of 0·735. The average molecular weight was determined by sedimentation equilibrium[4] at 12,500 r.p.m. to be 63,000 ± 4,000. It was shown, however, that although thrice crystallized, this preparation contained two protein fragments, one component representing approximately 90 per cent of the total fraction: two-dimensional agar-gel diffusion studies showed two precipitin bands to be present. The two components were separated by filtration through 'Sephadex *G*-100' (Pharmacia, Uppsala, Sweden). The purified main fraction of the crystallizable protein had an average molecular weight of 49,000 by sedimentation equilibrium at 12,500 r.p.m.; in 0·2 M mercaptoethanol, the sedimentation velocity was not significantly altered. In 6 M urea, $S_{w,20}$ was 2·6 for this fraction and in 6 M urea containing 0·2 M mercaptoethanol, $S_{w,20}$ decreased to 1·7.

Immunoelectrophoresis revealed the main antigenic component of the crystallizable fragments to be the faster

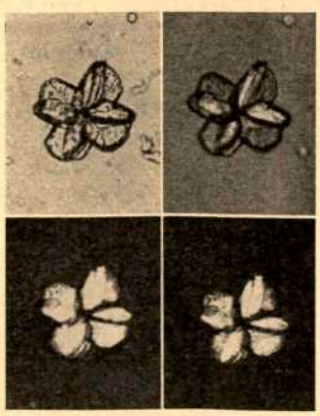

Fig. 2. In second and third crystallizations, crystals were flat and broad. Here, from third crystallization, 8 such crystals were joined and are viewed in various rotations of polarized light. (× *c.* 270)

of two antigenic determinants to be found in a papain digest of 7*S* γ_2-globulin. The 'slow' or *S* component of Edelman *et al.*[5] found in a papain digest of human 7*S* γ_2-globulin was separated from the 'fast' or *F* component in the digest[5] by chromatography on DEAE-cellulose in *p*H 7·6 phosphate buffer. The slow fraction was eluted directly from the column with phosphate buffer of ionic strength 0·01, and the *F* component was eluted by stepwise elution with buffer of ionic strength 0·4. Both fractions were further purified by gel-filtration, using 'Sephadex *G*-100'. In two-dimensional agar-gel diffusion, the *S* and *F* components gave a reaction of non-identity with each other, while the main component of the crystallizable fraction and the *F* component gave a reaction of identity. It would appear that the main crystallizable component represents the *F* fragment.

Tetanus antibody activity of the thrice-crystallized γ-globulin fragment and that of the *S* component were compared with that of unhydrolysed 7*S* γ_2-globulins. Total anti-tetanus antibody activity was determined by measurement of tetanus toxin neutralization in a mouse protection system (Division of Biologic Laboratories toxoid-coated red cells[6]. The neutralization test revealed that the immunochemically impure crystallized polypeptide had about 6 per cent of the activity of the original 7*S* γ_2-globulins while the *S* compound had an equal or slightly greater neutralizing activity than did the original 7*S* γ_2-globulin on a weight basis. In the hæmagglutination test, divalent activity of the crystallized fragment was 0·4 per cent that of the parent 7*S* γ_2-globulin, while the *S* component was devoid of divalent antibody activity. The antibody activity in the crystallizable fraction appeared to represent contamination with a univalent antibody component. The latter component was separated from the *F* component in the crystallized fraction by passage through 'Sephadex *G*-100'.

We wish to express our gratitude to Dr. Karl Schmid for determining the molecular weights.

Piloquinone: a New Phenanthrene-o-Quinone isolated from the Mycelium of *Streptomyces pilosus*

The mycelium of *Streptomyces pilosus* grown on a soy-bean meal containing medium produces several orange or red pigments. The principal one, which we propose to call 'piloquinone', crystallizes easily from a petrol ether or ether extract of the dried mycelium.

After recrystallization in chloroform-ether piloquinone is obtained as dark-red needles melting at 176°–178°. It is shown to be homogeneous by thin-layer chromatography on silicic acid.

The ultra-violet spectrum (in 95 per cent ethanol) has maxima at: λ_{max} 233 mμ ($\varepsilon = 32{\cdot}000$) and λ_{max} 286 mμ ($\varepsilon = 17{\cdot}000$) and a shoulder at 277 mμ ($\varepsilon = 15{\cdot}600$). The visible spectrum has maxima at 396 mμ ($\varepsilon = 4{,}075$) and 515 mμ ($\varepsilon = 5{,}560$). The infra-red spectrum (in 'Nujol') shows in the region of 1,500–1,700 cm^{-1} bands at: 1,570, 1,635 and 1,695 cm^{-1}.

Elementary analyses are in agreement with the formula $C_{21}H_{20}O_5$; the molecular weight 352 was confirmed by mass spectrometry. The pigment is easily bleached by sodium hydrosulphite and reoxidized by air; this indicates that it is a quinone. The easy formation of a quinoxaline $C_{27}H_{24}O_3N_2$ (m.p. 174°) after treatment with *o*-phenylenediamine suggests an *o*-quinone. A third oxygen atom is in a keto-group: piloquinone gives a mono-2,4-dinitrophenyl-hydrazone, $C_{27}H_{24}O_8N_4$, m.p. 254°; furthermore, reduction by $NaBH_4$ gives dihydropiloquinone, $C_{21}H_{22}O_5$, red brown needles, m.p. 230°, and Clemmensen reduction gives deoxy-dihydropiloquinone, $C_{21}H_{22}O_4$, red crystals, m.p. 175°; both these no longer show the CO band at 1,695 cm^{-1}.

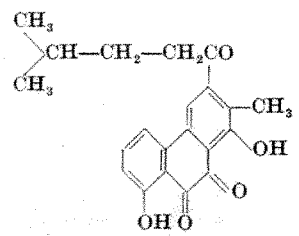
Two oxygen atoms of piloquinone are present in strongly chelated phenolic hydroxyl groups (peaks at 734 and 762 c.p.s. in the nuclear magnetic resonance spectrum) (the nuclear magnetic resonance spectrum was

ive acetyla-

tion of piloquinone gives a colourless tetraacetate $C_{29}H_{30}O_9$, m.p. 182° (still showing the carbonyl absorption at 1,690 cm^{-1}).

The five oxygen atoms of piloquinone are thus accounted for: two in the quinonoid system, two phenolic OH groups and one carbonyl.

Zinc dust distillation in an atmosphere of hydrogen gave phenanthrene and 2-methyl-phenanthrene melting at about 55°; moreover, after reductive acetylation of deoxy-dihydropiloquinone, a tetraacetate $C_{29}H_{32}O_8$, m.p. 164°, was obtained, having an ultra-violet spectrum very similar to that of phenanthrene.



It thus seems established that piloquinone is a dihydroxy phenanthrene-*o*-quinone.

The presence of an isocaproyl side-chain was shown by chromic acid oxidation[1] of piloquinone: vapour phase chromatography of the methyl esters of the volatile acids thus obtained showed the presence of methyl isocaproate, isovalerate and lower fatty esters.

The nuclear magnetic resonance spectrum of piloquinone shows a doublet at 57 c.p.s. (6 H) corresponding to the two methyls of the isocaproyl side-chain and a singlet at 133 c.p.s. showing the presence of a methyl group on an aromatic ring.

The nuclear magnetic resonance spectrum of piloquinone and of several of its derivatives also suggests the presence of three hydrogen atoms adjacent to each other on one aromatic ring, a fourth being alone on a substituted benzene ring.

All these properties are in agreement with formula I, which is consistent with biogenesis from a polyacetate precursor[2].

I

A detailed paper giving further structural proofs and degradation to a diphenyl derivative will be published in *Bull. Soc. Chim. France*.

Weever Venom

The venomous spines of the great weever (*Trachinus draco*) represent a great hazard especially to fishermen in areas where this fish is commercially important[1], since the wounds inflicted may cause severe and long-lasting pains[2].

Pharmacological[3] and serological[4] investigations have revealed little about the active principles. In the venom from the closely related lesser weever (*Trachinus vipera*), Carlisle[5] recently claimed to have found 5-hydroxytryptamine and a small molecular histamine releaser.

Our experiments have shown that the venom consists of three electrophoretically separable protein fractions. Evidence was obtained that noradrenaline, adrenaline, histamine and cholinesterase were present. Lecithinase and phosphodiesterase were not present.

When venom from the opercular spine of living weever was subjected to electrophoresis, the three spots shown in Fig. 1 were obtained. If the venom was diluted with a small volume of saline, coagulation occurred. Subsequent centrifuging and electrophoresis of the supernatant resulted in a single and faintly dyed spot at the application line indicating almost complete removal of the protein. The lability of the migrating components is also demonstrated by the tailing in Fig. 1.

The following experiments were all carried out with deep-frozen material. The opercular and dorsal spines were cut from living weevers (all about 30 cm long), immediately wrapped in aluminium foil, put on solid carbon dioxide and stored at $-20°$ C. For each experiment the venomous spines of two weevers were homogenized in Krebs–Ringer bicarbonate buffer using a small Waring blender.

Prior to adsorption on 'Amberlite *CG* 50' of the biological amines from an extract of venom, the protein was precipitated by the addition of an equal volume of ethanol. Elution of the amines and the subsequent paper chromatography were carried out according to Awapara *et al.*[6].

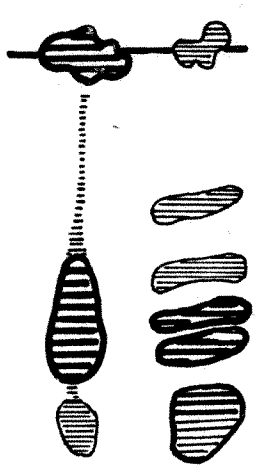

Fig. 1. Schematic drawing of an electropherogram run in 0·1 M veronal buffer *p*H 8·6, 200 V for 9 h. Dyed with amido black *B* 10. Left, venom; right, serum

The paper chromatogram revealed two spots, one of which was readily identified from its R_F value and colour reactions[7] as histamine. Similarly the other spot was identified as catecholamine[8]. As the paper chromatographic method used does not readily distinguish between the different catecholamines, further identification was carried out by a photofluorimetric method[9]. This revealed the presence of both adrenaline and noradrenaline in high concentrations.

Spraying of the chromatogram with 1-nitroso-2-naphthol reagent[10] did not reveal any 5-hydroxyindol derivative. In contrast to the lesser weever[5], therefore, 5-hydroxytryptamine does not seem to be present in significant concentrations in the great weever venom. The cholinesterase activity of homogenates was determined using standard manometric technique[11]. The high enzyme activity found in homogenized venomous spines (1,500 µl. carbon dioxide/100 mg wet wt.) and gill cover (3,000 µl. carbon dioxide/100 mg wet wt.) largely exceeded that obtained from fish muscle (300 µl. carbon dioxide/100 mg wet wt.). The homogenates were able to hydrolyse acetyl-, butyryl- and acetyl-β-methyl-choline, thus indicating the presence of both acetyl- and butyryl-cholinesterase. In a control experiment using gill cover from cod (*Gadus callarius*) no cholinesterase activity could be demonstrated.

The extracts of venom were examined for phosphodiesterase and lecithinase since these enzymes are common components of venoms from the animal kingdom. Using the methods of Boman and Kaletta[12] no activities could, however, be demonstrated. The reported hæmolytic properties of weever venom[4,13] can therefore scarcely be due to lecithinase.

Weever stings are known to produce ischæmia with subsequent hyperæmia, effects which may be explained by the amines present. These compounds will have a net effect according to their individual quantities and their rate of penetrating the surrounding tissue. In the initial ischæmic period the catecholamines, being vasoconstrictors, evidently are dominating. Since monoaminoxidase is present subcutaneously, the catecholamines are catabolized and the effect of histamine will prevail and produce hyperæmia. Admittedly this hyperæmia may at least partly be a reactive one.

The finding of a small molecular histamine releaser in the lesser weever venom was based on the weal and flare produced by the subcutaneous injection of a ninhydrin-positive substance eluted from a paper chromatogram[5]. Due to the close relationship between the two species, we suggest that this substance actually may be histamine itself.

The part played by cholinesterase in venoms from the animal kingdom has not been accounted for. We suggest that the high concentration of cholinesterase in the venomous spine and surrounding gill cover possibly reflects a cholinergic mechanism involved in the production of the venom.

The substances reported here are suggested to represent only a part of the toxic principles of the great weever venom, as the function of the protein fraction has been only partly accounted for. The coagulability of the proteins is evidently important, since the clot formed will greatly resist washing out. This view is in accordance with the prescriptions for the treatment of weever stings, which always state that good care should be taken to remove "traces of integumentary sheet" or "spongy white material" left in the wound. The clot will also promote a long-lasting effect of the inherent active principles as the diffusion into the surrounding tissue evidently will be retarded. Further, as it is well known that proteolytic enzymes are involved in coagulation processes, a significant part of the toxic principle may be related to the presence of such enzymes, as they may act further in the victim's tissue and split off toxic peptides. In this connexion, it is interesting to note that an enzyme promoting the coagulation of bovine plasma recently has been demonstrated and purified from Russell's viper venom[14].

We thank Mr. G. Dannevig, head of State Biological Station, Flødevigen, Norway, for his help during this investigation.

Ferulic Acid as a Component of a Glycoprotein from Wheat Flour

It has already been shown that the water-soluble wheat flour pentosans can be separated by DEAE-cellulose [illegible] into five fractions: a pure arabinoxylan

cipal glycoprotein fraction (No. 2) could be [illegible]. This fraction contains 80–90 per cent polysaccharide (components: xylose, arabinose and galactose) and 10–20 per cent proteins. The ultra-violet absorption spectra show in addition to the protein maximum a weak maximum at 320 mμ which disappears on oxidation[3]. It was suspected that polyphenolic compounds are responsible for this maximum.

Various degradation reactions were investigated, therefore, in order to obtain low-molecular weight fragments containing phenolic components. Degradation of the glycoprotein-2 by pure proteolytic enzymes released no phenolic compounds but showed that they were most probably linked to the xylan chain rather than to the protein part. Degradation by these enzymes produced two polysaccharide fragments of entirely different composition, indicating that in glycoprotein-2 the two polysaccharides are linked together by a polypeptide bridge[5].

Phenolic compounds could be split off from the glycoproteins (unfractionated flour pentosans), however, by treatment with aqueous 0·5 M potassium hydroxide at 60° C during 90 min under nitrogen. The hydrolysate was acidified (*p*H 3·5), extracted with ether followed by a bicarbonate extraction. The ether extract from the acidified bicarbonate solution was investigated by thin-layer chromatography. Three phenol positive spots were detected (solvent[6]: benzene–methanol–acetic acid 90 : 16 : 8, R_F values 0·46, 0·58 and 0·66). One of the spots (R_F 0·58) could be positively identified as ferulic acid (R_F values in various solvents, colour reactions, ultra-violet spectra of the extracted spot). When the flour pentosans were gelled by addition of hydrogen peroxide prior to hydrolysis with alkali, no ferulic acid could be detected. It is, therefore, very likely that ferulic acid and possibly other phenolic compounds in the soluble pentosans take part in the oxidative gelation of aqueous flour extracts and therefore constitute other types of compounds in wheat flour readily attacked by oxidizing agents.

It is tentatively assumed that ferulic acid is linked to the xylan chain via ester bonds. The deposition of toxic ferulic acid[7] and possibly other phenolic compounds in cell wall polysaccharides might be another way of detoxication of these compounds in certain plants, formation of simple glycosides being, of course, the most common way[8]. Aliphatic acids (formic and acetic acid) have long been known to be deposited as esters in certain plant cell wall polysaccharides[8].

Sulphatases and Sulphated Polysaccharides in the Viscera of Marine Molluscs

Glycosulphatases are present in tropical[1] and British[2–4] molluscs. Molluscan preparations also contain chondrosulphatase[2,4], which may be an oligosaccharide sulphatase; but few examples of polysaccharide-sulphatases are known[5].

Recently the sulphatase activities of preparations from marine molluscs collected on the North Wales shore with respect to various sulphated carbohydrates of both high [illegible] weight have been studied. The

with the carbohydrate substrate [illegible] liberated sulphate was detected turbidimetrically[6]. Preparations from *Calliostoma zizyphinum* and *Patella vulgata* showed the widest range of activity, each liberating sulphate from D-glucose- and D-galactoso-6-sulphate, chondroitin sulphate *A* and fucoidin. Other polysaccharides, keratosulphate, carrageenin and mucilages from *Dilsea edulis* and *Porphyra umbilicalis*, were not desulphated. *Littorina littorea*[3] and *Mytilus edulis* preparations contained glycosulphatase, but were inactive against chondroitin sulphate *A* and the algal polysaccharide sulphates. *Buccinum undatum* and *Gibbula cineraris* were without action on the foregoing substrates.

It was of interest to consider the nature of the natural substrates for molluscan sulphatases and a further investigation had led to the isolation, from *Patella vulgata* viscera, of a sulphated polysaccharide(s), which is a substrate for the sulphatase preparation obtained from the same source. The polysaccharide material was obtained by extraction of *Patella* viscera with 5 per cent potassium chloride followed by trypsin digestion, Sevag deproteinization, dialysis and alcohol precipitation. It was further purified by precipitation with cetyl pyridinium chloride[7]. Sugars detected when the preparation was hydrolysed with acid were fucose, xylose and galactose. Fucose and xylose are not usually encountered in other than trace amounts in animal tissues and it is considered likely that the polysaccharides, in *Patella* viscera are derived, partially at least, from algal sources (where these sugars are common) which are ingested by the mollusc[8]. *Patella* sulphatases are thus regarded tentatively as digestive enzymes.

Patella viscera also contains a glucan, which is obtained by extraction with 10 per cent trichloroacetic acid, as well as enzymes, which degrade starch, maltose and cellobiose.

We thank Prof. Stanley Peat for his interest.

PHYSIOLOGY

Role of Adenosine Triphosphate in Muscular Contraction

Loaded frog's stomach muscle at first relaxes and then contracts when treated with dinitrophenol (DNP)[1,2]. It was presumed that the relaxation and the subsequent contraction produced by DNP were due to depletion of stores of adenosine triphosphate. In the present research ATP, ADP and AMP have actually been estimated under the foregoing conditions.

These experiments were performed on circular strips of the stomach muscle of the frog *Rana tigrina*. Two sets of experiments were performed. In the first set two lightly loaded pieces of muscle from the same stomach were used; one of them, which served as a control, was suspended in Ringer solution and the other in Ringer solution containing 0·5 mM DNP. After 90 min both pieces were analysed for phosphate esters when the DNP-treated muscle had contracted after preliminary relaxation. In the second set of experiments, two pieces of muscle were similarly suspended in Ringer solution containing DNP, and one of them, which served as a control, analysed after 90 min, and the other was changed to Ringer solution and analysed after the next 120 min. To estimate the phosphate esters, the ether-extracted cold trichloroacetic acid extracts of tissue were chromatographed on paper using the solvent system of Krebs and Hems[3], and the esters were located by the acid molybdate spray of Burrows *et al.*[4]. The spots were cut out and wet washed[5] and analysed according to Bartlett's heating method[6] but read at 660 mμ (ref. 7).

DNP, after an initial stimulation, causes the loaded frog's stomach to relax and then contract again; on removal of DNP, the reverse happens, the muscle first relaxes and then contracts (Fig. 1). There are two variations from this usual result; the tonic contraction *B* may be little marked, suggesting the presence of some inhibitor in the muscle, and the relaxation *Y* may also be little marked, the contraction *B* passing into *C* without intervening relaxation. During the tonic contractions *A* and *C*, the muscle contracts when stimulated with electric current and acetylcholine, and shows spontaneous contractions; during *B* there was no response to stimulation and no spontaneous activity. *A* and *C* are relaxed by adrenaline and cyanide, but *B* is resistant to both.

The phosphate ester content in μmoles/g wet wt. of control muscles not treated with DNP was: ATP 1·512 ± 0·058, ADP 1·561 ± 0·053, AMP nil. That of 10 muscles treated with DNP for 1·5 h and in a contracted state was: ATP 0·114 ± 0·014, ADP 1·446 ± 0·085, AMP 1·650 ± 0·079, indicating a decrease of ATP by 92 per cent. In the second set of experiments, the phosphate ester content of 10 muscles treated with DNP was: ATP 0·104 ± 0·012, ADP 1·407 ± 0·079, AMP 1·634 ± 0·083. That of 10 muscles afterwards changed to Ringer and kept for 2 h therein was: ATP 0·809 ± 0·058, ADP 1·642 ± 0·065, AMP 0·539 ± 0·067, showing a recovery of about 50 per cent in the ATP content.

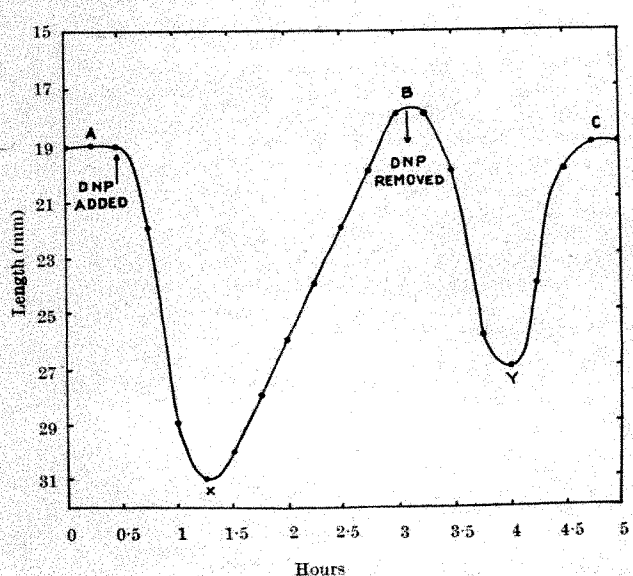

Fig. 1. Effect of 0·5 mM DNP on loaded frog's stomach muscle

These results suggest the two functions of ATP in unstriated muscle: (1) to provide energy for phasic contraction, active relaxation[1,2] and one kind of tone which is susceptible to asphyxia and metabolic inhibitors; (2) to keep the muscle relaxed. These probably correspond to two similar functions of ATP in the glycerol-extracted striated muscle[8].

In these estimations, an unidentified nucleotide phosphate ester band with R_F value 0·22 appeared and disappeared with the ATP band.

Inhibition of Thyroid Function by a Dithiocarbamoylhydrazine

Paget, Walpole and Richardson[1] described some biological effects of 1-α-methylallylthiocarbamoyl-2-methylthiocarbamoyl-hydrazine ('ICI 33828') in rats, dogs and monkeys and postulated a selective and reversible inhibition of pituitary gonadotrophic function. Similar results have since been obtained in mice[2]. In view of these findings we decided to investigate the effect of the compound on pituitary thyrotrophic function.

The effect on the goitrogenic action of methylthiouracil was investigated in rats using the increase in thyroid weight as an index of thyrotrophin production by the pituitary. The mean thyroid weight in a group treated with methylthiouracil and 'ICI 33828' was significantly less than that in a group given methylthiouracil and saline; but the treated group also showed a significant fall in total body-weight. Since the precise relationship between changes in total body-weight and thyroid-weight was not known these results were inconclusive. Attempts to modify the experiment so as to reduce the loss in body-weight were unsuccessful.

We decided, therefore, to investigate the rate of discharge of thyroid hormone labelled with iodine-131 from the gland in rats and mice treated with 'ICI 33828'. An injection of carrier-free $Na^{131}I$ was given intraperitoneally and after 48 h potassium perchlorate was added to the drinking water to prevent recirculation of iodine and to discharge inorganic iodide from the gland. On the following day and for either two or three days thereafter half the animals were injected subcutaneously with a suspension of 'ICI 33828' and half with the suspending medium alone. After 24 h the animals were killed and the radio-iodine content of their thyroid glands assessed.

It can be assumed that, at the beginning of treatment, the mean iodine-131 content of the thyroid glands of the mice in the control and treated groups is not significantly different. After any given time the mean iodine-131

remaining in the gland will be diminished by the amount which has been discharged. The total radioactivity remaining in the thyroid gland was therefore used as a convenient measure of thyroid hormone secretion. In each of the six experiments detailed in Table 1, with the exception of those using adult male mice, the iodine-131 content of the thyroid gland was significantly higher in the treated group than in the control. This was interpreted as being the result of a decrease in the rate of discharge of thyroid hormone during treatment with 'ICI 33828'.

Table 1

Animal	Dose 'ICI 33828' mg/day	No. of doses	Mean thyroidal ^{131}I counts/100 sec	Significance of difference from control. P*
Mice, female immature	0	4	1,534	
	1	4	1,965	< 0·01
Mice, female adult	0	4	17,820	
	1	4	32,660	< 0·02
Mice, male adult	0	4	1,726	
	1	4	1,611	> 0·1
Mice, male adult	0	4	554	
	1	4	582	> 0·1
Rats, male immature	0	3	864	
	1	3	1,443	< 0·001
	3	3	1,161	< 0·02
Rats, male adult	0	3	2,175	
	3	3	3,869	< 0·02

* Derived from t-test.

The effect of 'ICI 33828' on the discharge of iodine from the thyroid gland suggests a decrease in the secretion of pituitary thyrotrophin or an inhibition of its action on the discharge of thyroid hormone. A reduction in secretion seems the more likely because we have been unable to show a significant effect of 'ICI 33828' on the discharge of thyroidal iodine in response to exogenous thyrotrophin.

Since 'ICI 33828' contains thiourylene groups it might be expected, in addition to its postulated action on the pituitary, to have a direct effect on the trapping and protein-binding of iodine by the thyroid gland. This action was demonstrated in another series of experiments in which, in both rats and mice, the injection of 'ICI 33828' produced a significant decrease in thyroid uptake of radio-iodine. This effect could not be overcome by exogenous thyrotrophin given 24 h prior to the measurements in intact mice the endogenous thyrotrophin of which had been suppressed by the administration of thyroxine.

It seems likely, then, that 'ICI 33828' acts on thyroid function both by a direct effect on the gland and by influencing pituitary thyrotrophic activity. This combination of effects probably explains why we have found that the injection of doses up to 12 mg daily for 10 days caused no significant change in the thyroid weight of adult rats. Doses much smaller than this cause a marked block of uptake of iodine by the gland and might be expected to be goitrogenic if the drug did not at the same time suppress pituitary thyrotrophic activity. The mechanism by which it produces the latter effect and the absence of this effect in adult male mice remain to be explained.

We thank Drs. C. G. Downie and A. L. Walpole, of the Pharmaceuticals Division of Imperial Chemical Industries, Ltd., for supplies of 'ICI 33828'.

Absorption of Vitamin B_{12} – Glutamic Acid Mixture

In their recently published papers[1,2], Heathcote and Mooney have expressed the belief that the concept of intrinsic factor is incorrect and that the absorption of vitamin B_{12} is dependent on gastric proteolysis. According to them, vitamin B_{12} is absorbed as either small peptide or amino-acid units. In addition, they reported excellent results of oral treatment of pernicious anæmia with a vitamin B_{12}–glutamic acid mixture[3].

For a study of the absorption of vitamin B_{12}, the Schilling test is routinely used. It is, in our opinion, also suitable for investigation of the supposed promoting effect of L-glutamic acid on the absorption of vitamin B_{12}. Accordingly, we performed a series of Schilling tests with this objective.

The series consisted of ten patients with Addisonian pernicious anæmia. The diagnosis was established by blood picture, bone marrow findings and a 'Histalog' test meal. The following tests were made on each patient: (1) ordinary Schilling test with 0·5 μg of vitamin B_{12} labelled with cobalt-60; (2) Schilling test with the same B_{12} dose together with 10 μg of L-glutamic acid; (3) Schilling test with the same B_{12} dose and 30 mg of purified hog intrinsic factor (Abbott Lab., Inc.).

The results are presented in Fig. 1. In seven cases the values of the Schilling test with L-glutamic acid were not significantly different from the ordinary Schilling test values. In three cases the Schilling-L-glutamic factor values rose moderately, but even in these cases the increase was not of the same order as the increase in all cases of Schilling-intrinsic factor tests. The mean value of the ordinary Schilling tests was 1·0 per cent, that of the Schilling-L-glutamic acid tests 2·9 per cent and that of the Schilling-intrinsic factor tests 13·1 per cent.

In their therapeutic trial, Heathcote and Mooney[3] have used control periods of 10 and 13 days with crystalline vitamin B_{12} before starting therapy with the B_{12}–L-glutamic acid mixture. In both their cases the rise in hæmoglobin

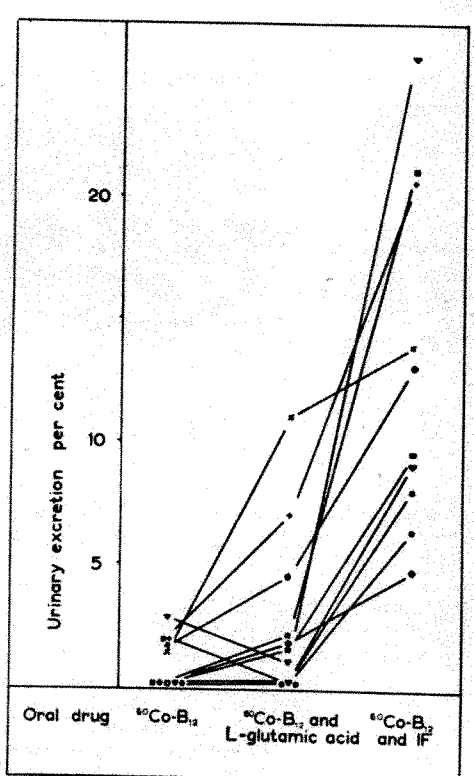

Fig. 1. Results obtained in the Schilling tests with vitamin B_{12} alone, with vitamin B_{12} and L-glutamic acid, and with vitamin B_{12} and intrinsic factor

and packed cell volume began on the first day of B_{12}–L-glutamic acid treatment. In our opinion, this rise occurred too early to have been an actual response to B_{12}–L-glutamic acid treatment. It appears more likely to have been an effect of the crystalline vitamin B_{12} therapy given during the preceding control period. On the other hand, we admit that the second reticulocyte response following B_{12}–L-glutamic acid treatment indicated that L-glutamic acid promotes the absorption of vitamin B_{12} to some extent at least.

Our results with Schilling tests, however, indicate that L-glutamic acid does not in general increase the absorption of vitamin B_{12}, or at least not to anywhere near the same extent as the intrinsic factor preparation. Accordingly, we do not find ourselves in agreement with Heathcote and Mooney and we cannot deny the existence of an "intrinsic factor".

Olli Heinivaara
Ilmari Palva

Second Medical Department,
University of Helsinki, Finland.

thcote, J. G., *Brit. Med. J.*, i, 232 (1961).
ney, F. S., *Second European Symp.*, Hamburg, rt, 1962).
F. S., *Nature*, **193**, 380 (1962).

The authors of the g communication state that "According to them [H te and Mooney], vitamin B_{12} is absorbed as either oeptide or amino-acid units". We trust that this mis retation of our actual beliefs is due to lingual difficulty does not imply that we believe in the peptide or amino- nature of vitamin B_{12} itself.

Dr. Heinivaara and Dr. Palva state her that the Schilling test is "suitable for investigation he supposed promoting effect of L-glutamic acid on the absorption of vitamin B_{12}". It is unfortunate that they do not give their reasons for this statement because the significance of their own work depends entirely on the validity of this assumption. We should particularly like to know why they think that this test—which actually measures the urinary excretion of radioactive vitamin B_{12}—necessarily gives a true measure of the amount absorbed? Can they demonstrate—as the Schilling test presumes—that all forms of vitamin B_{12} when absorbed into the blood stream are incorporated into the stores and blood-forming tissues at an equal rate? Furthermore, can the "flushing dose"—assuming that it dislodges some radioactive B_{12} from the serum—also release that which has been actively incorporated into the liver and blood-forming tissues? Unless they can produce such evidence, their own results can be equally well interpreted simply as demonstrating an improved retention or an increased "resistance to flushing" of radioactive B_{12} in the presence of glutamic acid. Do they also believe that the Schilling test is a better index of therapeutic efficiency than the type of test which we have used, whereby hæmatological progress is assessed? Has it in fact any physiological merit at all?

With reference to our work, Dr. Heinivaara and Dr. Palva "admit that the second reticulocyte response following B_{12}–L-glutamic acid treatment indicated that L-glutamic acid promotes the absorption of vitamin B_{12} to some extent at least". They go on to state that "In both their cases the rise in hæmoglobin and packed cell volume began on the first day of B_{12}–L-glutamic acid treatment. In our opinion, this rise occurred too early to have been an actual response". Examination of the figures in our paper will show, however, that in case 49 (Fig. 1) neither the hæmoglobin nor the packed cell volume was estimated during the first four days of treatment with B_{12}–L-glutamic acid mixture, and that in case 52 (Fig. 2) a fall in both hæmoglobin and packed cell volume was recorded in the first estimation performed after the commencement of B_{12}–L-glutamic acid treatment.

Finally, it may be of some interest to mention, briefly, the present state of health of the two patients who formed the basis of our communication. Both are still on the same form of therapy, are well, and have no neurological symptoms. Case 49 has now been maintained for 973 days on an average daily dose of 28 μg of the mixture (expressed as B_{12} content). At present his hæmoglobin is 91 per cent and packed cell volume 40 per cent. Case 52 has been maintained for 885 days on an average daily dose of 24 μg of B_{12}–glutamic acid mixture. His hæmoglobin is 107 per cent and packed cell volume 44 per cent. A third patient (case 62) has also been treated with B_{12}–glutamic acid, since our earlier publication. He is a man aged seventy-five who had, on admission, a hæmoglobin of 52 per cent and packed cell volume of 25 per cent. He has been treated for 639 days with an average daily dose of 16 μg of the mixture. At present his hæmoglobin is 95 per cent and packed cell volume 40 per cent.

In conclusion, although we have no particular desire to undermine any faith which they may hold in "intrinsic factor", might we suggest to Dr. Heinivaara and Dr. Palva that a critical re-appraisal of the value of the Schilling test, as a basis for their belief, might not be entirely without profit?

Increase of Trypsin Inhibitor in Serum during Pregnancy

In normal pregnancy increased quantities of trypsin inhibitor are excreted in the urine, especially during the second and third trimester, followed by a rapid decrease to normal after parturition[1].

Excretion of trypsin inhibitor seems a response to stress, since it is increased after various forms of stress and after administration of ACTH or glucocorticoid hormones[2,3]. The amount excreted appears to be regulated by the concentration of glucocorticoids (endogenous or exogenous) in the body[3,4]. Hence, it is also believed that the increased trypsin inhibitor excretion observed in pregnancy is produced by an increase in glucocorticoid production.

The physiological mechanism of the excretion of trypsin inhibitor is unknown, but we have found that in certain forms of stress (surgical) the increase in trypsin inhibitor excretion parallels an increase in trypsin inhibitor concentration in blood serum, suggesting that variations in trypsin inhibitor excretions reflect variations in serum concentration of the same inhibitor[5]. In order to substantiate this concept we wish to report an increase of trypsin inhibitor concentration in serum during pregnancy, corresponding in pattern to the variations in urinary trypsin inhibitor excretion[1] and in serum concentration of glucocorticoid hormones[6].

The estimation of trypsin inhibitor in serum was performed as before[5]. One trypsin inhibitor unit represents the amount which inhibits 1 μg of a preparation of crystalline, pure trypsin containing 24·4 Anson units per g (kindly supplied by the NOVO Laboratories, Copenhagen).

Blood samples were obtained from 11 normal women and from 47 women with normal pregnancies of different durations. Blood was centrifuged immediately after spontaneous coagulation, and serum was stored at −8° C until analysed.

The results (Table 1) show great individual variations in the serum concentration of trypsin inhibitor. This was also encountered in the amount excreted in the urine during 24 h (ref. 1). Thus, in the non-pregnant group the serum concentration ranged from 300 to 1,965 trypsin inhibitor units per ml. with an average value of 1,140 units per ml. (*S.E.*, 134). In the pregnant groups the deviations tended to be slightly less. The difference between the average concentration in the first trimester

Table 1. Concentration of Trypsin Inhibitor in Units per ml. Serum in Pregnant Women

Non-pregnant	1st trimester	2nd trimester	3rd trimester
300	1,060	1,510	525
765	1,230	1,590	1,380

		2,340	2,460
		2,340	2,475
		2,370	2,520
			2,520
Average: 1,140 ± 134 (*S.E.*)	Average: 1,565 ± 98 (*S.E.*)	Average: 2,005 ± 58 (*S.E.*)	Average: 1,985 ± 112 (*S.E.*)

(1,565 units per ml. with the *S.E.* 98) and in non-pregnant women is not statistically significant.

The average concentrations in the 2nd and 3rd trimesters are both statistically different from the non-pregnant group ($P < 0.001$) and the 1st trimester ($P < 0.01$ and $P < 0.02$, respectively). The small difference between the average values in the 2nd and 3rd trimesters is caused by one single person, who deviated considerably from the remaining individuals in the group.

The increase in trypsin inhibitor in serum during pregnancy parallels in time the increased urinary excretion observed before[1]. These results are comparable with those obtained in surgical stress as mentioned above. Hence, it is suggested that the increase in trypsin inhibitor excretion in urine is caused by the increased serum concentration of trypsin inhibitor and not by a possible alteration of the kidney function, respective to the treatment of the trypsin inhibitor. It is further suggested that not only the increase in urinary excretion of trypsin inhibitor but also the increase in serum trypsin inhibitor concentration in pregnancy are caused by an increase in glucocorticoid production.

The trypsin inhibitor responsible for the increase in trypsin inhibitor concentration in serum and trypsin inhibitor excretion in urine during stress and pregnancy could be called the stress-regulated or the glucocorticoid-regulated trypsin inhibitor[5]. Also the hyaluronidase inhibitor in serum increases during pregnancy[7]. This observation is of interest because the trypsin inhibitor in urine is a hyaluronidase inhibitor[8], suggesting that the substances, which produce increase in hyaluronidase-inhibiting activity and in trypsin-inhibiting activity of blood are identical.

IMMUNOLOGY

Delayed Hypersensitivity to a Conjugate of Polytyrosine and its Inhibition by Haptens

Recent investigations concerning the nature of the antigenic determinants involved in delayed hypersensitivity to hapten–protein conjugates have pointed to the important part played by the protein carrier[1,2]. In addition, some aspects of the heterogeneity of the response have been clarified[3]. In recent experiments reported by us[4], guinea pigs were immunized with arsanilic acid (ars) coupled to guinea pig serum albumin. They reacted with the same hapten coupled to many unrelated proteins, suggesting a high degree of hapten-specificity. Positive reactions elicited by heterologous haptens coupled to guinea pig serum albumin were also noted and considered to be a response to antigenic determinants produced or revealed by the chemical process of conjugation with diazonium salts.

In order to limit to some extent the heterogeneity of response attributed to antigenic determinants arising from the non-repeating amino-acid sequences present in proteins as well as from the many different sites available for hapten conjugation, attempts were made to induce delayed hypersensitivity to haptens conjugated to a polymer of a single amino-acid.

This communication is concerned with investigations of delayed hypersensitivity produced to polytyrosine (obtained from Yeda Research and Development Co., Rehovoth, Israel) conjugated with diazotized arsanilic acid in a ratio of 5 moles arsanilate per mole of polytyrosine. A total of 100 μg polytyrosine–azobenzenearsonate (ars–polytyr) emulsified in complete Freund adjuvant containing killed mycobacteria was injected in a total volume of 0·1 ml. in the four foot pads of 400 g white guinea pigs. Two weeks later, skin tests were performed with 1 μg nitrogen amounts of conjugates prepared from a variety of proteins and arsanilic acid. Some typical results seen in Table 1 illustrate what appears to be a large measure of hapten specificity. Thus, arsanilic acid conjugated to proteins as diverse as insulin and ribonuclease produced delayed reactions which were, if anything, larger than the reactions produced by the immunizing antigen itself. These results may be compared with those reported[4] previously for immunization with a conjugate prepared from arsanilic acid and guinea pig serum albumin, in which a large degree of hapten specificity was also noted. In this latter case, however, conjugates prepared from heterologous protein carriers usually produced smaller reactions than did the immunizing antigen. Both these results stand in striking contrast to the narrow range of carrier specificity observed with other haptens, such as *p*-aminobenzoic acid and picryl chloride[1], in which conjugates prepared from heterologous protein carriers were unreactive.

Table 1. Skin Reactions to Azobenzenearsonate-conjugated Proteins in Guinea Pigs immunized with 100 μg Ars–Polytyrosine

No. of animals	Delayed reactions* to skin test antigens: ars–polytyr (50 μg)	ars–gelatin (1 μg N)	ars–GSA (1 μg N)	ars–ribonuclease (1 μg N)	ars–insulin (1 μg N)	ars–elastoidin (1 μg N)

5	13	14	—	—	18	—
5	13	—	—	—	—	13

* Average induration and erythema (mm).

It seemed evident from these findings that a large portion of the reaction spectrum produced by immunization with ars–polytyr might be directed towards the azobenzenearsonate group. To provide further evidence for this, attempts were made to suppress the delayed reaction to this moiety by the administration of simple haptens. The most obvious hapten, other than arsanilic acid itself, was considered to be its conjugate with tyrosine. Accordingly, equimolecular amounts of diazotized arsanilic acid and *N*-acetyltyrosine were allowed to react in cold alkaline solution and the resulting dye

precipitated by acidification. Similar dyes were prepared by conjugation with *N*-benzoyltyrosine as well as the other aromatic amino-acids *N*-acetyltryptophan and *N*-acetylhistidine.

In Table 2 are seen the results of skin tests with ars–guinea pig serum albumin before and after hapten administration in animals immunized with ars–polytyr. With the dose-levels used, a striking suppression of reaction was observed only with the ars–*N*-acetyltyrosine, so that 24-h reactions to skin tests performed immediately after intracardiac injection of this hapten consisted only of occasional erythema alone. It is of interest that arsanilic acid itself in doses four times as large was not inhibitory. Also inactive was the conjugate prepared from the *N*-benzoyl derivative of tyrosine. Because of the unknown effects of differences in hapten solubility and rates of excretion, it cannot be stated with certainty that these results are due to steric interference of the benzoyl group with the binding by the reactive component in delayed hypersensitivity and the tyrosine–azobenzenearsonate group. Similarly, conclusions concerning the inability of haptens prepared from histidine and tryptophan to suppress delayed hypersensitivity must also await determinations of their *in vivo* solubility and persistence. Nevertheless, these results provide strong confirmatory evidence for the conclusion that the size of the antigenic determinant responsible for the reactions investigated here lies between arsanilic acid itself and tyrosine–azobenzenearsonate.

Table 2. Skin Reactions to Ars–Guinea Pig Serum Albumin (GSA) before and after Administration of Haptens in Guinea Pigs immunized with Ars–Polytyrosine

No. of animals	Hapten given (1×10^{-5} moles)	Delayed reactions* to skin tests with 1 μg N ars–GSA: Pre-hapten	Immediately post-hapten	24 h post-hapten
5	ars–*N*-acetyltyrosine	15	0†	11
3	ars–*N*-benzoyltyrosine	14	13	12
4	ars–*N*-acetyltryptophan	12	9	8
4	ars–*N*-acetylhistidine	12	11	10
4	arsanilic acid plus *N*-acetyltyrosine (4×10^{-5} moles each)	13	12	—

* Average induration and erythema (mm).
† No induration, 8 mm erythema.

The delayed response to conjugates prepared with proteins undoubtedly represents a more complex reaction pattern[3,4], since some degree of reactivity is probably directed towards antigenic determinants of the protein carrier and some towards determinants consisting of hapten plus the amino-acids at its site of attachment. If this analysis were correct, it would follow that hapten inhibition of delayed reaction would be observable only in the event that the major contribution to the reaction was made by the antigenic determinant to which the hapten was related. To test such a hypothesis, inhibition investigations were conducted on guinea pigs immunized with ars–guinea pig serum albumin and tested with this antigen before and after intracardiac injection of ars–*N*-acetyltyrosine. The results in Table 3 show that in 3 of the animals a slight decrease was noted. However, in no case was there so marked a suppression of reaction as that seen in the animals immunized with ars–polytyr. An eight-fold larger dose of arsanilic acid was completely non-inhibitory.

Table 3. Skin Reactions to Ars–Guinea Pig Serum Albumin (GSA) before and after Administration of Haptens in Guinea Pigs immunized with Ars–GSA

1	ars–*N*-acetyltyrosine (1×10^{-5} moles)	17	9
2	,,	19	11
3	,,	19	9
4	,,	10	12
5	,,	19	20
6	,,	16	20
7	arsanilic acid (8×10^{-5} moles)	11	7
8	,,	13	15
9	,,	16	20

* Average induration and erythema in mm.

Since the degree of sensitivity achieved by immunization with ars–polytyr and ars–guinea pig serum albumin cannot be quantitatively ascertained, comparisons of the suppressive effect produced by haptens in the two cases is attended by some uncertainty. Nevertheless, the results reported here provide suggestive evidence of the narrowed range of antigenic determinants resulting from immunization with conjugates prepared from a polymer of a single amino-acid. Secondly, and of considerable importance, the demonstration of suppression of delayed hypersensitivity by simple haptens in these animals introduces a powerful tool for the elucidation of the nature of the interactive forces involved in delayed hypersensitivity.

PATHOLOGY

Influence of Urethane on Susceptibility to Leukæmia Induction by Graffi Virus in Adult Mice

The occurrence of leukæmia in mice of low-leukæmic strains, injected with urethane (ethyl carbamate) at birth or soon after, has recently been reported by several investigators[1]. Adult animals, on the contrary, do not seem to be very susceptible to the leukæmogenic activity of urethane, though there is some contradictory evidence[2]. However, urethane has been shown to be highly effective in increasing the incidence of leukæmia induced in adult mice by other agents, such as X-ray, œstrogenic hormones, or methylcholanthrene[3].

The enhancing effect of urethane on radiation leukæmogenesis was well demonstrated by Berenblum and Trainin[4], who observed a remarkable increase in leukæmia in *C57BL* mice receiving repeated doses of urethane after total-body irradiation. Since no comparable results were obtained when the sequence was reversed (that is, urethane prior to X-ray), these authors suggest, in line with the two-stage theory of carcinogenesis, that, in leukæmia induction, urethane acts as a 'promoting' agent. In further experiments[5] the same investigators observed leukæmogenic activity of urethane also when administered to non-irradiated recipients previously implanted with various tissues from irradiated isogenic donors. It was therefore suggested that urethane operates as a co-leukæmogenic agent, possibly by converting into an active leukæmogenic virus a 'transmissible factor' appearing in a precursor stage under the 'initiating' influence of X-radiation.

On this basis, experiments were undertaken to test in a simple experimental system the possible influence of urethane on virus leukæmogenesis. Since in preliminary investigations we obtained evidence that mice of certain low-leukæmic strains did not develop leukæmia after inoculation at adult age with cell-free extracts containing Graffi virus, it was decided to investigate whether the susceptibility to induction of leukæmia by this virus could be modified by supplementary treatment with urethane.

Male and female *C57BL* and *C3Hf/Gs* mice, three months old, were divided in four groups and treated as follows: One group received intraperitoneally four doses of 1 mg/g of urethane at intervals of 3–4 days; 24 h after the last injection, the animals were inoculated intraperitoneally with 0·10 ml. of cell-free extract obtained from leukæmic tissues of mice bearing leukæmia induced by Graffi virus. In another group the sequence of the

treatment was reversed, the interval between the inoculation of the extract and the first dose of urethane being 4 days. The remaining two groups, which served as controls, were given injections of cell-free extract alone, and of urethane alone, respectively. The Graffi virus was originally obtained from a leukæmic *C57BL* mouse received in August 1961 from Prof. Graffi's laboratory and carried since then in this laboratory by inoculation of cell-free extracts in new-born mice of the same strain. The extracts were prepared from homogenates of thymus, lymph nodes, and spleen, as a 20 per cent suspension in saline, centrifuged at 1,400*g* and then at 7,000*g*. The preparations used in this experiment yielded about 90 per cent leukæmia when injected in new-born animals of several strains, including mice of *C57BL* and *C3Hf/Gs* strain.

Table 1. INFLUENCE OF URETHANE ON LEUKÆMOGENESIS BY GRAFFI VIRUS IN *C57BL** AND *C3Hf/Gs** ADULT MICE

Treatment	*C57BL*			*C3Hf/Gs*		
	Total No. of mice	No. of mice with leukæmia	Leukæmia incidence (%)	Total No. of mice	No. of mice with leukæmia	Leukæmia incidence (%)
Urethane	24	2	8	20	1	5
Virus	38	2	5	27	0	0
Urethane followed by virus	19	3	16	28	2	7
Virus followed by urethane	18	10	55·5	20	0	0

* Incidence of spontaneous leukæmia less than 1 per cent.

The results, which refer to a 10-months' period of observation from the time of treatment, are shown in Table 1. The mean latent period in all the four groups was about 7 months after treatment. A slight prevalence of leukæmia was observed in female mice. Histologically, leukæmia was of the lymphoid type in all animals except in three *C57BL* mice of the group receiving virus prior to urethane in which a myeloid leukæmia developed. In one of them the neoplastic tissue exhibited grossly the greenish appearance characteristic of chloroleukæmia. The occurrence of myeloid leukæmia in mice of this group strongly suggests that the leukæmic disease is of viral origin, since in our laboratory this type of leukæmia has never been observed in *C57BL* strain except after inoculation of Graffi virus. On the other hand, the prevalence of lymphoid leukæmia in our experiments is not surprising, since it has been found that the type of leukæmia resulting from injection of Graffi virus in new-born mice of several different strains is mainly conditioned by the host environment (unpublished results).

The remarkable increase of the incidence of leukæmia obtained in *C57BL* mice only when urethane was administered after the virus seems almost exactly like that observed by Berenblum and Trainin[4] using X-radiation and urethane, thus confirming under different experimental conditions a 'promoting' action of this chemical. That both exposure to X-radiation and inoculation of a cell-free extract containing an active virus have the same effect with regard to the capability of urethane to influence leukæmogenesis in adult *C57BL* mice may add support to the hypothesis that a virus is involved in X-ray leukæmogenesis[6]. However, since in our experiments there is no doubt that the virus concerned is an active, complete virus, the 'promoting' effect of urethane could be explained either as a direct influence of the drug on infected cells or, more generally, in terms of modification of the degree of susceptibility of the host to the leukæmogenic action of the virus. The possibility that in animals receiving combined treatment leukæmia would result from activation by urethane of a different, pre-existing virus harboured in normal *C57BL* mice can readily be ruled out in view of the negligible leukæmogenic activity exhibited by urethane when administered alone in the same strain of mice.

We thank Prof. A. Graffi for sending us *C57BL* mice with virus-induced leukæmia and Prof. I. Berenblum for his interest. This work was supported in part by grants from Consiglio Nazionale delle Ricerche, Roma, and NATO Research Grants Programme. One of us (L. C–B.) is also holder of a fellowship from the Lady Tata Memorial Fund.

Mast Cell Reaction and 5-Hydroxytryptamine Content in the Skin of Syrian Golden Hamsters painted with 9 : 10-Dimethyl-1 : 2-benzanthracene

IN the skin of mice painted with chemical carcinogens a remarkable accumulation of mast cells is usually observed in the altered dermis. Cramer and Simpson[1] first observed that the accumulating mast cells acquire a strong primary golden-yellow fluorescence in ultra-violet light, a property which is not possessed by normal skin mast cells of mouse.

In experiments previously reported[2], designed to investigate the development of mast cell reaction during subsequent stages of skin chemical carcinogenesis in Swiss mice, we found that the increase of mast cell number closely paralleled the degree of intensity of mast cell fluorescence and the rise of skin-level of 5-hydroxytryptamine (5-HT). In addition, prolonged treatment with acetone (the usual solvent of 5-HT) prior to formol fixation was found to abolish completely the fluorescence of mast cells. These findings gave support to the hypothesis, first advanced by Riley[3], that the fluorescence acquired by dermal mast cells under such experimental conditions was due to a remarkable increase of the amount of 5-HT contained in the mast cells. Actually, a similar strong golden-yellow fluorescence is a characteristic feature of enterochromaffin cells, that is, the main physiological cellular source of this amine, as well as of 5-HT examined *in vitro*. However, the fluorescing mast cells fail to give positive results when tested with the argentaffin reaction of Masson–Hamperl, which is considered a sensitive method, although not entirely specific, for evidencing histochemically 5-HT in enterochromaffin cells (unpublished observations). Such results leave some doubt on the identity of the fluorescing material with 5-HT.

Since 5-HT has been found only in mast cells of mice and rats and not in those of other animal species[4], it was considered of interest to test whether in hamsters, which are also susceptible to skin carcinogenesis, the mast cell reaction would occur with morphological and biochemical characteristics comparable with those observed in mice.

In experiments reported here, Syrian golden hamsters, originally obtained from ARSAL Co., Rome, and bred at random in this laboratory, were used. Twenty animals of both sexes, aged 8 months, received twice a week on the

clipped skin of the back 0·10 ml. of a 1 per cent solution of 9:10-dimethyl-1:2-benzanthracene (DMBA) in paraffin oil. The animals were killed 7 weeks after the beginning of the treatment, when they had received 14 applications of DMBA. As controls, 20 untreated animals of both sexes were killed at the same age of the experimental group. Bioassay of the 5-HT content of the skin and histological or ultra-violet examination of mast cells were performed according to the methods previously described[2].

In comparison with controls, a remarkable accumulation of mast cells was detected in the dermis of the painted area in all the treated animals. The mast cell reaction was practically comparable with that observed in previous investigations in mice, although less pronounced. The accumulating mast cells appeared smaller and less granulated than normal hamster mast cells and located mostly beneath the hyperplastic epidermis. However, when the sections were examined in ultra-violet light both the normal and reacting mast cells failed to exhibit any fluorescing property. Moreover, the determination of 5-HT skin level did not reveal any difference between control and treated animals, the values obtained being less than μgm/gm 0·08 in both groups.

These findings indicate that no production of 5-HT occurs in normal skin mast cells of hamsters as well as in mast cells appearing in the dermis during carcinogenic treatment in these animals. In skin carcinogenesis of mice, as already stated, the close parallelism between golden-yellow fluorescence of mast cells and high content of 5-HT in the skin suggested that the increased level of this compound was the factor responsible for the fluorescing properties acquired by the reacting mast cells. The results of the experiments recorded here give further support to this hypothesis, since in hamsters painted with DMBA neither increase of 5-HT nor appearance of fluorescence in the accumulating mast cells was observed in the skin. On the other hand, the lack of appreciable amounts of 5-HT in mast cells of DMBA-treated hamsters seems to indicate that this amine plays no significant part in the mast cell reaction developing in the course of chemical skin carcinogenesis.

RADIOBIOLOGY

Cæsium-137 Content of Lambs

The cæsium-137 γ-activity of 10 lambs, which had been used previously to investigate some relationships between potassium-40 content and composition[1], was measured concurrently with potassium-40 γ-activity on the Los Alamos human counter[2]. The lambs averaged 88 lb. in live-weight and were purchased from a feed-lot at La Jara, in southern Colorado, in March 1960. The counting conditions have been described earlier[1]. The γ-counts from the upper and lower channel settings were entered on I.B.M. cards, and a computer tabulated and printed the cæsium results as μμc./*g* potassium[3]. Calculations were based on previously determined calibration curves for the counter.

The cæsium content of the 10 live lambs and their components are presented in Table 1. The increase in the cæsium/potassium ratio which was recorded after the lambs had been washed resulted from the removal of a large amount of potassium from the surface of the lambs by the washing process[1]. The results (Table 1) show that, when the cæsium-levels were converted to a per kilogram of tissue basis, little cæsium was removed by washing. Results indicate that the cæsium/potassium ratio in the washed lambs and their components was fairly constant, which would be expected as cæsium is metabolically similar to potassium[4]. This resulted in a higher concentration of cæsium per unit of muscular tissue than in the live lambs, as the lean tissue also has a higher concentration of potassium[1].

Table 1. Cæsium-137 Content of Ten Live Lambs and their Components

Item	Mean	*S.D.*	Range
Live unwashed (μμc. cæsium-137/g K)	58·0	10·6	41·8–74·5
Live washed (μμc. cæsium-137/g K)	84·8	17·9	60·2–121·0
Dressed carcass (μμc. cæsium-137/g K)	81·5	23·0	43·0–122·4

Separable lean (μμc. cæsium-137/kg K)	79·5	18·1	59·1–107·7
Live unwashed (μμc. cæsium-137/kg tissue)	155·4	24·1	126·3–182·8
Live washed (μμc. cæsium-137/kg tissue)	148·7	21·4	118·8–183·3
Separable lean (μμc. cæsium-137/kg tissue)	236·6	54·3	167·8–323·1

Counts for separable fat and bone on the lower channel were so close to background that several of the samples were estimated to have a negative cæsium content and all results on these tissues were obviously inaccurate. For this reason they have not been reported.
* Mean is based on 9 observations as one negative value was discarded. If a value of zero is used for the negative observation, the mean becomes 87.

The levels of cæsium reported are similar to those found in cattle tissue in 1957–59 in the United States[5], in pigs and calves prior to 1962 in Canada[6,7] and in human beings prior to 1961, largely from the United States[4]. However, the values are very much lower than those observed in Norway and Sweden for beef[8,9], horse[9], mutton[9], pork[9], reindeer[9,10], and, to a lesser extent, man[10,11]. As all these observations were made prior to the recent nuclear weapons test series of the U.S.S.R. and the United States beginning in August of 1961, it would appear that these levels resulted from earlier weapon tests. Differences may be due to different world fall-out patterns, time interval from previous atomic tests and different eating habits.

Lead-210 and Polonium-210 in Human Tissues

It has recently been shown[1] that appreciable amounts of lead-210 and polonium-210 may occur in certain human foodstuffs as a result of deposition from the atmosphere of long-lived radon decay-products (Table 1). Absorption of these products may therefore occur by both inhalation and ingestion, but, although measurements of the activity of lead-210 in many human bone samples have been reported[3–6], the ratio of polonium-210 to lead-210 in bone and the activities of these nuclides in human soft tissues have been reported in only a few samples[1,3,7,8]. This communication describes the results of preliminary radiochemical estimations of polonium-210 and lead-210 in human bone and soft tissue samples.

Table 1. Radon Decay Products

	Nuclide	Half-life (ref. 2)	Decay
Radon	Rn-222 (Rn)	3·823 d	α
Short-lived daughters	Po-218 (RaA)	3·05 m	α
	Pb-214 (RaB)	26.8 m	β^-
	Bi-214 (RaC)	19·7 m	β^-
	Po-214 (RaC′)	160 μs	α
Long-lived daughters	Pb-210 (RaD)	20 y	β^-
	Bi-210 (RaE)	5·0 d	β^-
	Po-210 (RaF)	138·4 d	α
Stable lead	Pb-206	—	—

The method used was similar to that of Black[7]. Up to 80 g of wet tissue were digested with nitric and perchloric acids, care being taken to keep the temperature below 200° C because of the volatility of polonium. From a final solution, 0·5 N in hydrochloric acid, polonium was electrochemically deposited on silver foil and the α-activity was measured in a low background scintillation counter[9]. The specificity of the separation for polonium-210 was checked by α-spectroscopy of several of the foils, using the α-spectrometer which is described elsewhere[10]. By low-level β-counting for bismuth-210 in an aged deposit on silver from an equilibrated lead-210 solution, it was shown that less than 0·01 per cent of lead-210 was deposited under the plating conditions used in the tissue analyses. Hence, lead-210 was estimated in some of the tissue samples by deposition of the polonium-210 from the tissue solutions several months after the first deposition. Reproducibility was checked by several estimations of polonium-210 and lead-210 in samples from the same tissue. The overall yield was estimated by spiking one member of each of ten pairs of samples with an equilibrated lead-210/bismuth-210/polonium-210 solution and the measured overall yields for the first and second depositions were 90 ± 5 per cent and 90 ± 9 per cent respectively. The average activities of the tissues determined in this manner are as shown in Table 2.

Table 2. Po-210 and Pb-210 in Human Tissues

Tissue	Po-210 pc./100 g wet.		Po-210/Pb-210
Vertebra	1·7	(9)	0·82 0·43
Liver	1·0	(4)	3·1 1·8
Kidney	0·71	(2)	8·9 4·1
Spleen	0·32	(3)	1·8 0·4
Lung	0·30	(2)	—
Skeletal muscle	0·11	(5)	—
Testis	0·33	(4)	—

The figures in parentheses (Table 2) indicate the number of specimens of each type of tissue analysed. The ratios in column 3 are from individual determinations. Taking account of the uncertainties in the yields and the counting statistics, the probable errors of the individual determinations were less than 10 per cent for polonium-210 and 20 per cent for lead-210. The extreme values from separate determinations for a given type of tissue were within a factor of 2·5 of the mean value tabulated.

A few observations may be made in the light of these results. The average polonium-210 concentration in the bone samples is comparable with previously reported values and there are indications that the lead-210–polonium-210 series may not be in radioactive equilibrium in vertebræ. This is in keeping with the findings of Black[7] and Holtzman[3]. The latter author has suggested that the lead-210 concentration (per gram ash) in vertebræ is close to the average for the whole skeleton. On this basis, assuming an ash content in vertebræ of 21 per cent, a total skeletal ash of 2,800 g and, from the foregoing, a polonium-210/lead-210 ratio in vertebræ of 0·6, the skeletel burden of lead-210 is approximately 400 pc.

The results of tracer studies with animals and a few human beings, summarized in the I.C.R.P.[11] tables, have indicated that polonium-210 may be concentrated in the soft tissues, particularly liver and kidney, and the foregoing measurements suggest that this is also the case at lower levels, the polonium-210 being measurably in excess of lead-210. α-spectroscopic measurements on other tissue samples[1] have demonstrated that polonium-210 is in excess of other α-emitters. The measurements reported here give average values for polonium-210 activity in the major soft tissues higher than those spectroscopic determinations, probably because of volatilization of polonium in the dry-ashing procedure required for the spectroscopy.

If the concentration in those types of soft tissue not measured here is comparable with that measured in skeletal muscle, the foregoing results indicate an average body burden of polonium-210 in the range 330–450 pc. with at least 20 per cent of the activity in the soft tissues. The upper and lower limits correspond to the assumptions that the more highly mineralized cortical portion of the skeleton has a polonium-210/lead-210 ratio equal (*a*) to that in the trabecular region, taken here as 0·6, or (*b*) to unity, respectively.

The radiation dose rate from the concentrations of lead-210 (β-energy, 17 keV maximum) and polonium-210 (α-energy, 5·30 MeV) in tissues, reported here, is due predominantly to the polonium-210 α-particle. The *in vivo* activity of bismuth-210 (β-energy 1·16 MeV maximum) is difficult to measure because of its rather short half-life. However, since bismuth does not appear to be concentrated very markedly in any of the larger organs[11], it seems unlikely that redistribution of bismuth-210 following the decay of lead-210 would affect the validity of the foregoing statement. A polonium-210 concentration of 0·1 pc./100 g wet. tissue gives a dose rate of approximately 1 mrem/y, so estimates of the dose rate to the various soft tissues from the measured activities may readily be obtained from Table 2. Comparison of these dose rates with those from radium-226 plus short-lived daughters and the radium-228 series in human bone and soft tissues[12] indicates that the rem dose rate from polonium-210 in bone may be comparable with the rem dose rate from those nuclides and, in soft tissues, the rem dose rate from polonium-210 may be more than an order of magnitude greater than that from radium-226 plus short-lived daughters and the radium-228 series.

BIOLOGY

Culture of Single Mammalian Cells

The single-cell culture method of mammalian cells was established by Puck *et al.*[1], and is now applied in cell physiology and genetics. Edlinger[2] has simplified this method, using a rubber-stoppered bottle without 5 per cent carbon dioxide incubator. However, this was used only for the nutritionally non-exact *L* strain cell: the method has also been used for the nutritionally more exact HeLa strain *S*3 clone[3] as well as the other two strains, and has provided results applicable to the cell-cloning technique. This communication is concerned with the technical details of this method, and presents a nutritional investigation of the single-cell culture medium for bottle technique.

All the cell strains used were those maintained in lactalbumin hydrolysate Hanks's solution medium containing bovine serum. The basal culture medium through the single cell culture test was new Eagle's medium[4] and the serum added to the foregoing medium was the bovine serum inactivated at 56° C for 30 min. The whole medium component was adjusted to *p*H 6·8 with 5 per cent carbon dioxide in air to avoid possibly the alkaline shifting of medium *p*H during the incubation period, and it was sterilized through a porcelain filter. For the test 36 cm² virus-plaque bottles were used. Four ml. of the culture medium were put in each bottle and 300 trypsin-dispersed cells were inoculated to the culture medium. The culture was incubated at 37° C under rubber-stoppered conditions for 14 days. The experimental results are expressed as plating efficiency, which is the percentage ratio of the performed colony number to the inoculated cell number. The colony count was carried out after the 14th culture day, the colonies being stained with Giemsa (Fig. 1).

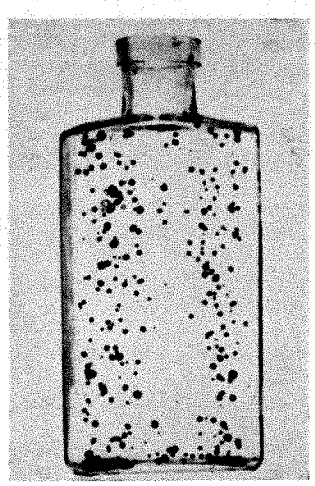

Fig. 1. The colonies of HeLa–*S*3 cell developed in a square bottle after 14 days of culture

Before considering the experimental results, it should be noted that the serum used in this test had a critical controlling effect. Accordingly, all the sera used were checked roughly for the plating efficiency beforehand and any toxic serum was omitted from the test. At the outset of this work the effect of the serum concentration to the plating efficiency was tested. The medium containing 20 per cent serum showed the best results through all the cell strains examined over the range tested. In the past, tests of plating efficiency of HeLa strain with 20 per cent serum medium was 67–88 per cent. The results of *DK* strain (established dog kidney strain) and *FL* strain (established human amnion strain) were similar to those for HeLa strain, while those of *L* mouse strain usually showed 100 per cent with 20 per cent serum medium.

Table 1. Effect of Nutritive Supplements on the Plating Efficiency of HeLa-*S*3 Cell in Eagle's Medium supplemented with 5 per cent Whole Serum or 15 per cent Dialysed Serum

Serum	Supplement*	Plating efficiency	Serum	Supplement*	Plating efficiency
5% Whole serum	Nothing	0	15% Dialysed serum	Nothing	8·5
	Vitamin B_{12} (1)	4·0		Cholesterol (5)	6·8
	Thymidine (2)	0		L-Serine (6)	5·7
	Folinic acid (3)	24·0		(4)	4·8
	Lactalbumin hydrolysate (4)	25·0		(5)+(6)	11·8
	(1)+(2)	8·0		(4)+(5)+(6)	22·5
	(1)+(3)	4·5		(1)+(2)+(3)+(4)+(5)+(6)+Protamine insulin	40·0
	(2)+(3)	3·5			
	(1)+(2)+(3)	45·0			
	(1)+(2)+(3)+(4)	25·0			

* Concentration of each supplement is as follows (mg/l.): Vitamin B_{12}, 0·02; folinic acid, 0·1; thymidine, 2·4; lactalbumin hydrolysate (Nutritional Biochemicals Co.), 300·0; cholesterol, 0·8; L-serine, 10·0; protamine insulin, 200 unit/l.

When the serum concentration was decreased to 5 per cent and its plating efficiency dropped to zero, the addition of lactalbumin hydrolysate (Nutritional Biochemicals Co.) and the combination of thymidine, folinic acid and vitamin B_{12} to the medium could increase the plating efficiency considerably (Table 1). Also when the serum was dialysed for 24 h against Earle's balanced salt solution, following Puck's method[5], the plating efficiency of 15 per cent dialysed serum medium was quite low. But the addition of lactalbumin hydrolysate, folinic acid, vitamin B_{12}, thymidine and protamine insulin to the medium in addition to cholesterol[5] and serine[4] increased the plating efficiency to each additive, while a combination of them together could raise the plating efficiency still further (Table 1). These findings show that under a closed system the nutritional requirement for colony formation is somewhat different from the results reported by Eagle[6] and Puck[1].

The plating efficiency of the present method is not complete. But using the foregoing technique, a special 5 per cent carbon dioxide incubator was not needed; an ordinary incubator was good enough. The cell-cloning technique was simply performed with a platinum loop and was successfully applied for cloning the antibiotic-resistant HeLa strain cell clone and the HeLa clone more sensitive to adenovirus[7].

Skin Biopsy for Cell Culture

One of the most useful tissues available to the human geneticist for cell culture is skin. It is plentiful, easy to grow, remains diploid for several months, and can be frozen, stored for probably years, then thawed and re-cultured[1]. What is needed for large-scale family or population studies is a simple, rapid, relatively painless procedure for obtaining suitable skin biopsies. Just such a procedure, using an electric rotary punch, is described in the literature by Urbach and Shelley[2]; but few investigators outside the field of dermatology seem to be aware of the technique. We have had such good results with an adaptation of the punch drill that we call attention to it in this communication and present our results to date. The procedure is as rapid and simple as a venipuncture, and certainly no more painful. No anæsthesia or suture is required, and the biopsy can be performed in the clinic, the office, or the patient's home.

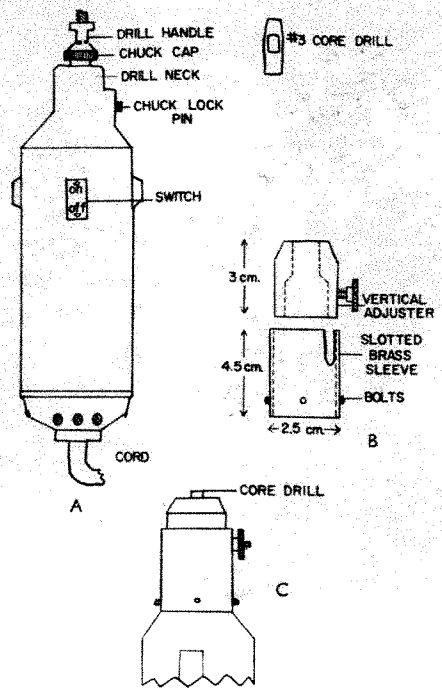

Fig. 1

The drill and component parts are illustrated in the diagrams. Fig. 1*A* depicts the electric drill with the drill handle in place in the chuck. (Moto-Tool model No. 2. 110 V a.c.—d.c. 65 amp. Manufactured by Dremel Manufacturing Co., Racine, Wisconsin: obtainable from the Scientific Glass Apparatus Co., Inc., 735 Broad Street, Bloomfield, New Jersey.) The drill handle and the core drills are part of a punch biopsy set (Martin *M–H* Biopsy Set, a United Product, Port Chester, New York). The 5-5 in. handle from the set must be cut to about 2 cm in length and tooled down to fit the chuck. Fig. 1*B* shows the slotted brass sleeve and the hollow brass vertical adjuster made for us by a machinist. Fig. 1*C* shows the assembled apparatus ready to operate. The brass sleeve is bolted on to the neck of the drill and the vertical adjuster is telescoped inside it to set the depth of the incision. A core drill is autoclaved along with a pair of forceps and a pair of sharp scissors.

The biopsy is performed as follows: the skin is swabbed with alcohol or zephiran, rinsed with sterile saline, and dried with sterile gauze. Almost any area of the body can be used. We have biopsied the buttocks of babies, the back medial to the upper border of the scapula, the flexor surface of the forearm[3] and the deltoid region. The core drill is grasped with the sterile forceps and screwed on to the drill handle. The chuck lock pin will prevent the chuck from rotating as the drill is tightened. Then the vertical adjuster is telescoped into the brass sleeve, taking care not to contaminate the sterile core drill. The desired depth is maintained by the nut on the vertical adjuster. We have found that a depth of 2–3 mm is adequate for cell culture. The rotating drill is momentarily touched to the skin with a 'flick of the wrist' motion. The small core of skin is then lifted gently with the sterile forceps and snipped off quickly with the scissors.

Our experience is as follows: using a No. 3 core drill (3 mm diam.) and a depth of about 2 mm, we have obtained 21 biopsies, all of which were successfully cultured in modified Eagle's medium with 20 per cent human serum and 5 per cent bovine embryo extract ultra-filtrate. Each specimen was cut into as many small pieces as possible and incubated at 37° C in an atmosphere of 5 per cent carbon dioxide in air. Seventeen of the skin specimens were collected by one of us in Sardinia and sent by air to Baltimore in medium, unrefrigerated. The trip took 8 days, and handling of the packages was far from ideal. One specimen arrived stuck on the side of the glass tube out of the medium and quite dried out. Although slow in starting, it has since grown well. We have, however, lost one specimen by contamination before any investigations were made, and one has never grown well and will probably be lost.

In each case we enquired about pain. The electric drill itself is virtually painless. The snipping of the pedicle usually produced some slight discomfort, but only for an instant. One sleeping infant did not even waken during the entire procedure. With the No. 3 drill, bleeding was either absent or slight, and easily stopped by a minute or two of pressure. The site was covered for 2 days by a simple band-aid, and the resultant scar is barely noticeable in most cases. One of us is using the apparatus for sweat gland biopsy[2], and uses a No. 5 core drill (5 mm diam.) with depths up to 1 cm. Even in these cases pain was minimal, and bleeding was arrested by a simple pressure dressing.

This investigation was supported in part by U.S. Public Health Service research grants *GM*05945, *A*494 and *A*6278 from the National Institutes of Health.

Cultivation of Mouse Embryos *in vitro*

EXPERIMENTAL embryology of mammals is greatly restricted by the difficulties of growing mammalian embryos *in vitro*. Despite recent successes with the cultivation of mouse and rabbit eggs[1], techniques for the cultivation of post-implantation embryos have not hitherto advanced beyond those devised by Jolly and Lieure[2], and Nicholas and Rudnick[3]. Jolly and Lieure obtained development of rat and guinea pig embryos explanted into homologous serum at stages between primitive streak and a few somites. They report that of their explanted rat embryos 37 per cent developed an embryonic axis with a rhythmically beating heart, but only 9 per cent a functioning circulation. None formed limb buds or a functioning allantoic circulation. Nicholas and Rudnick[3] appear to have had a similar degree of success with rat embryos explanted into heparinized rat plasma and embryo extract.

We have obtained much better results by growing mouse embryos on chick plasma clots in an atmosphere consisting of 5 per cent carbon dioxide in air. For a few of the cultures the oxygen was also increased (to about 60 per cent) and this improved the results. The clots were made by adding one part of embryo extract to three parts of chick plasma. The embryo extract was obtained from either 18-day mouse or 13-day chick embryos; both gave equally good results. The embryos to be cultured were obtained from *C3H*, hybrid and other genetic strains of mice mated 8–9 days previously, and ranged from primitive streak stage to about six somites. They were dissected free of the decidua and of Reichert's membrane but were not separated from the yolk sac or ectoplacental cone. The whole explant therefore consisted of a small

Table 1. Number and Percentage of Embryos surviving to Different Stages in Culture

			Percentage of No. explanted
Stage attained in culture	No. explanted	126	
	8 or more somites; beating heart	107	85
	Yolk sac circulation	98	78
	16 or more somites	58	46
	Allantoic circulation	30	24
	Limb buds	34	27

sphere of yolk sac with the embryo at one pole and the ectoplacental cone at the other (Fig. 1).

Each explant was placed on a clot in a drop of embryo extract diluted with an equal volume of Tyrode solution containing an extra 1 per cent glucose. During incubation the fluid within the yolk sac rapidly increased in volume so that the diameter of the yolk sac sphere, which at the time of explantation was about 1 mm, increased after 48 h to 3–4 mm. As it grew it digested a cavity in the clot and sank into it. Despite the close contact between the yolk sac and the clot no firm adhesion was formed between the two. Cells of the ectoplacental cone, however, attached firmly to the clot and migrated for a short distance into and over it.

We have cultured 126 embryos. They were usually examined 24 h after explantation and again after 48 h. By 24 h most of the embryos had developed a complete embryonic axis with more than 8 pairs of somites, a beating heart and a functioning embryonic and yolk sac circulation. The allantois had fused with the ectoplacental cone forming the allantoic placenta, and in some of the cultures blood could be seen circulating in the allantois. After 48 h many of the embryos still had a functioning blood circulation and a few had developed limb buds and 20 or more pairs of somites (Figs. 2 and 3). Histological examination showed them to have well-differentiated internal structures (Fig. 4). Circulation of the blood often continued for a further few hours and a rhythmical beating of the heart for considerably longer, but no further development occurred. Table 1 shows the number of embryos developing to different stages.

The proportion of explanted mouse embryos that develop in our cultures, and the amount of growth and differentiation that occurs, is similar to that obtained with chick embryos of equivalent age when cultured by the standard methods. It should now be possible, therefore, to apply to mammalian embryos many of the embryological techniques that have been used so successfully on

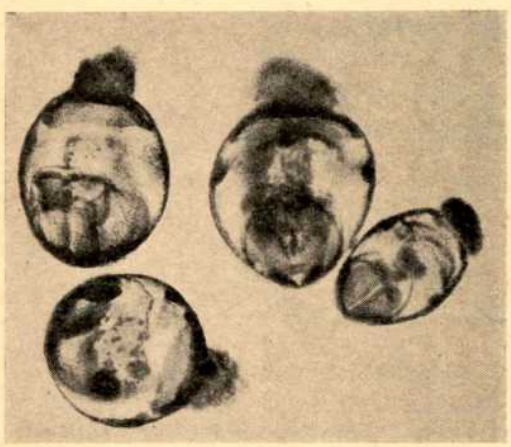

Fig. 1. Embryos as explanted. Amnion, yolk sac and most of ectoplacental cone left intact, but Reichert's membrane removed (× 24)

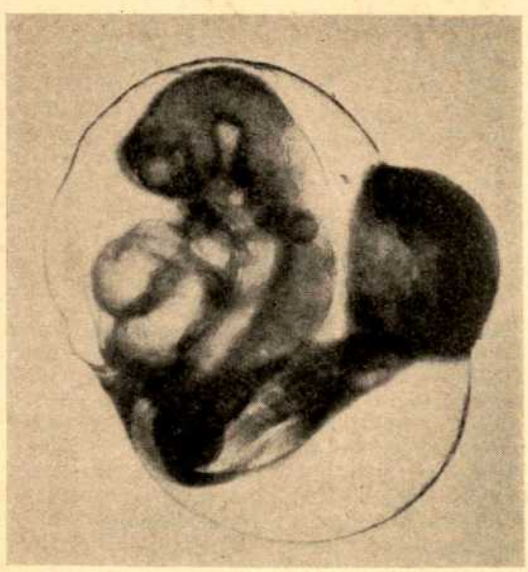

Fig. 2. Embryo explanted at the 5-somite stage and grown in culture for 48 h. More than 20 somites, optic and otic vesicles have developed, together with functioning yolk sac and allantoic blood circulations (× 24)

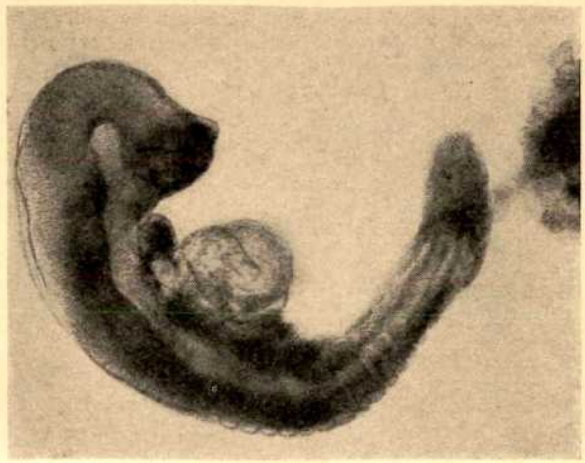

Fig. 3. Embryo explanted at the 6-somite stage and grown in culture for 48 h. Membranes removed before fixation (× 24)

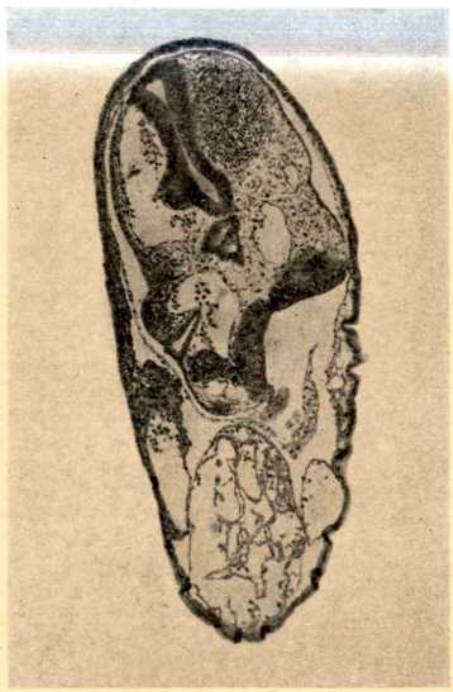

Fig. 4. Embryo explanted at the head fold stage and grown in culture until 18 somites developed. Section through brain, pharyngeal pouch and allantois (× 60)

the chick. We are at present studying the physiological requirements of mouse embryos *in vitro* and the possibility of grafting tissues from one embryo to another.

Thyroid Gland and Temperature Tolerance Relationships in Cold-blooded Vertebrates

Although the thyroid gland is of extreme importance in the metamorphosis of amphibians, its function in cold-blooded vertebrates in general is still obscure[1]. Several workers have suggested that thyroid hormones enable poikilotherms to withstand changes in environmental temperature. For example, Evropeitzeva[2] reported that larvæ of *Coregonus lavaretus ludoga* withstood exposure to 29° C for 5 min after treatment with 0·033 per cent thiourea, whereas untreated animals died. Suhrmann[3] found that immersion in a solution of thiourea increases the upper lethal temperature in the goldfish, *Carassius auratus*. Dent and Lynn[4] also indicated that the thyroid may play a part in tolerance to changes in temperature. But the most striking report in this field comes from the work of Fortune[5,6], who has reported that in the minnow, *Phoxinus phoxinus* L., the thermal death point is raised some 10° C by treatment with thiourea. She states: "*Phoxinus* already treated with thiourea for 3 days, were subjected to a rise in temperature of 10° C (that is, to 33° C) over 2 days. They survived indefinitely at this temperature and appeared normal, the controls dying under such conditions between 23° C and 24° C". On the other hand, La Roche and Leblond[7] state that the ability of salmon parr to withstand rising temperatures is impaired by radiological thyroidectomy and is restored by the administration of thyroid powder.

As a preliminary to further work on these aspects of thyroid physiology, and in an attempt to confirm and extend the work of Fortune, one of us (J. M. D.) set out to repeat the work on minnows already described. Fish were obtained from Lake Windermere in September and October and a series of experiments was started. A repetition of Fortune's protocol gave thermal death points of 29°–31° C in both thiourea-treated and control fish. The preliminary treatment with thiourea was then extended, first to 10 days at 23° C and afterwards to 27 days at 15° C without effect on the thermal death point. In the latter experiment all fish died at about 30° C whether the rise was sudden (15°–30° C a day) or more gradual (5° C a day). In conjunction with these studies, tests of the temperature tolerance of a fish with an extensive, naturally occurring goitre and a group of fish that had been treated with sodium thyroxine at a concentration of 1 in 10^7 at 23° C for 3 days were carried out. All died at about 30° C, indicating that neither depression nor elevation of thyroid function affects temperature tolerance in this type of experiment. This work was extended to include tadpoles of *Xenopus laevis*, and it was found that neither thiouracil treatment nor surgical thyroidectomy enabled the tadpoles to withstand temperatures higher than 34°–36° C, at which control specimens also died.

We have more recently repeated part of this work and have once again found no elevation of the thermal death-point. Minnows, received from Lake Windermere in mid-September, were kept at 15° ± 1° C for about a month and were fed on 'Bemax' fish food. On October 17, 20 fish, each about 5 cm in length, were selected and divided into two groups of 10. Each group was put in 4 l. tap water in a 5-l. beaker and the beakers were submerged to the level of their contents in a constant-temperature bath at 15° C. The temperature of the bath was gradually raised from 15° C to 19° C on the first day and from 19° C to 22° C on the second. By the end of the second day one fish in each beaker was dead. On the third day the water in one beaker was replaced with fresh tap water and the other with tap water containing 0·05 per cent thiourea, both at 22° C, and the temperature was raised to 23° C, at which level it was maintained for 3 days. This concluded the conditioning period. The gradual elevation of the temperature was then continued. After 22·5 h the temperature reached 27·6° C and the first fish died. Between 22·5 and 31 h the temperature was raised to 29·7° C and the progressive mortality of the treated and control groups was virtually identical. At 31 h and a temperature of 29·7° C one control and one experimental fish remained alive. By 45 h and without raising the temperature further all the fish were dead.

These findings are not sufficiently extensive to serve as a firm basis for sweeping conclusions, particularly in the face of some contradictory evidence; but clearly they give support to the view that hypofunction of the thyroid gland of the minnow does not enhance the ability of the fish to withstand exposure to lethal and sub-lethal temperatures under the conditions described here. However, they do not necessarily run counter to Evropeitzeva's findings since her fish were exposed to near-lethal temperatures for only 5 min.

This work, which was supported in part by U.S. Atomic Energy Commission contract *AT* (40–1)–2000, was carried out at the Gatty Marine Laboratory of the University of St. Andrews.

Rapid Detection of the Pathogenicity of Phytopathogenic Pseudomonads

Most bacterial plant diseases are caused by bacteria belonging to the genus *Pseudomonas*. A number of saprophytic pseudomonads occur in large amounts on the surface of the plant (*Pseudomonas fluorescens*, *Ps. denitrificans*, etc.). Therefore, isolation of phytopathogenic pseudomonads from the diseased plant is difficult. Generally the morphology of the colonies, the biochemical properties[1], the antigenic structure[1] and the phage sensitivity[2] of the pathogenic and saprophytic pseudomonads are so similar that they can scarcely be distinguished on the basis of the foregoing characteristics. In practice the pathogenicity test is the sole reliable method which can be used for identification. To carry out pathogenicity tests one must have suitable hosts, but in this case the entire procedure of artificial infection in the greenhouse is tedious. Testing of woody plants is particularly difficult.

An 'injection-infiltration' method has been developed as a rapid test of pathogenicity. Potted tobacco plants instead of the normal hosts of the pathogens are used

Fig. 1. Infiltration by injection of an intact tobacco leaf

for the tests, which can easily be carried out even in winter time. *Nicotiana tabacum* var. White Burley plants are particularly suited for the tests but other tobacco varieties will do as well. Infection is carried out as follows: colonies of the *Pseudomonas* type which have been obtained by plating from diseased plants are suspended one by one in 3-ml. sterile tap-water. The suspension should contain about 10^7 bacterial cells/ml. Adjustment of the number of cells can be carried out by the use of a densitometer or, after some practice, also by subjective judgment. These suspensions are then injected by fine hypodermic needle into the intercellular spaces of the tobacco leaf (Fig. 1). Older leaves are more suitable for injection than the young ones. The injection can be made more easily near the lateral veins of the leaf (lower surface), where the tissues are thicker. The carefully injected suspensions will spread over a larger surface usually surrounded by the bigger veins. When several bacterium strains are under investigation these can be injected one by one into the various inter-veinal areas of the leaf (Fig. 1). Thus 10–12 different bacterial strains can be injected into a single leaf. After infiltration, the infiltrated water is evaporated from the intercellular spaces and the leaf regains its original appearance.

24–48 h after injection with phytopathogenic bacteria the injected leaf areas die off and in 3–4 days the treated tissues become entirely dry and white. Saprophytic bacteria do not induce necrosis in the leaf. After proof of pathogenicity, knowing the host plant from which the isolation has been made, the bacterium can be identified.

The method has the advantage that the investigations can be carried out on intact plants. Until now infiltration of intact plants was difficult. Complicated procedures were needed for the infiltration of potted plants. Much material to be infiltrated was needed for the infiltration either of whole plants or of detached leaves. The injection infiltration method makes it possible to feed the leaf with substances in small amounts and even dilution series can be injected into various parts of the same leaf. In view of this the method is particularly suitable for plant physiological experiments.

++, Total necrosis; +, partial necrosis; +−, weak necrosis; −, no necrosis; *, weak yellowing.

By the use of the method described here a number of pathogenic and saprophytic *Pseudomonas* strains derived from different localities were investigated. The bacteria were injected into tobacco leaves in different cell-concentrations. The results are shown in Table 1.

It may be seen that all phytopathogenic bacteria-induced deaths of cells occur at a concentration of 10^6 cells/ml. With inocula of a lower cell number macroscopic symptoms were not obtained. Infiltration of less-concentrated suspensions has led to the development of small local lesions extending to a few cells which could be seen by 10- to 12-fold magnification. The number of these small lesions was proportional with the number of bacteria infiltrated.

Pseudomonas tabaci, the causal agent of the 'wildfire' disease of tobacco, evokes the development of symptoms different from those induced by other pathogenic bacteria. On one hand the dead parts of the leaves do not bleach; on the other, the cells die more slowly. The lower the cell number of the inoculum, the slower the death of the tissues in the case of injection with *Ps. tabaci*.

Saprophytic bacteria do not cause death of cells. Infiltration with cell numbers as high as 10^8–10^9 cells/ml. results later on in a weak yellowing of the treated areas.

The detection of pathogenicity with the foregoing method is based on the hypersensitive reaction of the tobacco leaf. A hypersensitive reaction of a similar nature has already been described for bean pods infected with bacteria[3,4].

MICROBIOLOGY

Sucrose-fermenting Strains of *Clostridium septicum*

Several authors[1–5] have described *Clostridium septicum* as an organism which does not ferment sucrose. Smith[6], describing the fermentation reactions of strains of *Clostridium septicum*, mentions that some strains do ferment sucrose but that they need several days for sufficient acid to be produced to be detectable by the usual indicators.

During the investigation reported here, strains of *Clostridium septicum* were isolated from various samples of soils, and a collection of 52 strains formed the basis of the work. The strains were tested for fermentation of sugars. The sugars used were glucose, fructose, galactose, maltose, lactose, sucrose, inulin, glycerol, mannitol and salicin.

Sugars were added to peptone water as Seitz filtrates to give 1 per cent (w/v) solutions. Andrade's indicator was incorporated to detect change in acid. The sugar media were inoculated with 4 drops of an overnight culture of *Clostridium septicum* grown in sugar-free media. Two sets of sugars were tested with each strain of *Clostridium septicum*. One set was incubated under anaerobic conditions in a McIntosh and Fildes jar. In the other set anaerobiosis was brought about by the addition of a sterile iron nail about 0·5 in. long to each tube. Both conditions were found to be equally effective for testing the ability of *Clostridium septicum* to ferment sugars. The tubes were examined for acid and gas production in 24 h and 48 h.

Fifty of the strains produced acid and gas from glucose, fructose, galactose, maltose, lactose and salicin; sucrose, inulin, mannitol and glycerol were not fermented by them. Two of the strains produced acid and gas from sucrose in addition, which was detectable in 24 h. Both these strains were pathogenic to guinea pigs, and cultures obtained from the heart blood of the dead guinea pigs retained the ability to ferment sucrose. The fermentation of sucrose and glucose was very similar: this is a significant finding as the fermentation of sucrose by *Clostridium chauvoei* and the inability of *Clostridium septicum* to ferment sucrose are used as one of the distinguishing tests between the two, which are very similar in other reactions and also possess a common antigen.

Membrane Stability and Salt Tolerance in Gram-negative Bacteria

THE ability of a bacterium to tolerate any particular set of ionic conditions is likely to be determined in part by the outermost permeability barrier of the organism. This barrier, which is usually a lipoprotein membrane, is in contact with the extracellular environment and must remain functional under all conditions which permit growth of the organism. It has already been shown that the cell envelopes (or membranes) of two Gram-negative bacteria, one a marine organism (N.C.M.B. 845) requiring moderate concentrations of salt and the other a halophil (*Halobacterium halobium*) requiring high concentrations of salt, are unstable at low ionic strengths. The structural integrity of these two types of envelope depends, to a different degree in each case, on ionic strength or the concentration of bivalent cations[1,2]. The work recorded here was undertaken to determine if cation-sensitive instability of bacterial membranes is a general phenomenon and if there is evidence of a correlation between membrane properties and salt tolerance of the growing organism.

Gram-negative bacteria isolated from marine and other sources were used. For determination of salt tolerance they were incubated at 30° in stagnant media containing peptone (1 per cent w/v) and sodium chloride (0, 1, 2, 4 and 8 per cent w/v). Growth was assessed by inspecting the tubes after 1, 2, 3 and 6 days. The organisms and their salt tolerances are listed in Table 1, which shows that all the non-marine bacteria grew without added salt and one of them (*Proteus* sp.) tolerated 8 per cent sodium chloride; on the other hand, none of the marine bacteria grew with less than 1 per cent sodium chloride. Minimal salt requirement was the only conspicuous and constant difference between the two groups of organisms. For the preparation of cell envelopes, bacteria were grown for 22–24 h with aeration in a medium (500 ml.) containing peptone (1 per cent w/v). The medium was prepared in sea-water for the marine organisms and distilled water for the others. Two organisms, the *Pseudomonas* sp. and *Escherichia coli*, were grown also in half-strength and full-strength sea-water respectively. Envelopes were prepared in cold distilled water as previously described[3]. Envelope breakdown was measured turbidimetrically at 700 mμ in a solution containing *tris* (hydroxymethyl) amino methane buffer (*p*H 8·0, 0·0125 M) and sodium

Table 1. LIMITS OF SODIUM CHLORIDE CONCENTRATION (%) FOR GROWTH OF GRAM-NEGATIVE BACTERIA

Organism	Minimal	Maximal	Optimal*
Marine			
11 (N.C.M.B. 845)	1	8	4
12	1	8	2–4
13	1	8	4–8
14	1	8	2–4
26	1	8	8
56	1	8	1–4
60	1	4	4
67	2	4	2–4
68	4	4	4
72	1	8	2–4
73	1	8	2–4
74	4	8	4–8
Non-marine			
Pseudomonas sp.	0	4	1
Escherichia coli	0	4	1–2
Achromobacter sp.	0	4	1–2
Proteus sp.	0	8	1–2
Serratia sp.	0	4	0
Spirillum undula	0	1	0–1
Spirillum serpens	0	1	0

Marine bacteria are listed by their catalogue number in the culture collection of C.S.I.R.O., Division of Fisheries and Oceanography, Cronulla, Sydney. They were mostly motile rods, probably related taxonomically to N.C.M.B. 845. Exceptions were an agar-digesting species of *Cytophaga* (No. 68), an organism with a low incidence of branching (No. 72) and a very pleomorphic organism of average length about 2μ (No. 74). Halophilic bacteria were omitted from the survey because it has been shown that breakdown of the membrane *Halobacterium halobium* is not autolytic as in N.C.M.B. 845 but instead consists of non-enzymatic dissociation into subunits (ref. 2).
* Optimal salt concentration was assessed from rate of development of turbidity and final maximal turbidity reached by the cultures.

chloride (0·01 M) at 35°. The amount of envelope breakdown was expressed as the percentage reduction in turbidity after 20 min at 35°. Protein was estimated by the method of Lowry *et al.*[4].

No direct correlation was demonstrated between envelope lysis and salt tolerance but, by analogy with N.C.M.B. 845[3], it was thought that lysis would be affected by the amount of protein in the cell envelopes. Envelope protein lay between about 21 per cent (*S. serpens*) and about 85 per cent (*E. coli* grown in sea-water). There was no statistically significant correlation between envelope protein and the extent of lysis. There was, however, a significant relation between 'specific lysis' (lysis (per cent)/protein (per cent)) and salt tolerance. For maximal salt concentration tolerated during growth the mean values of specific lysis were: 1 per cent sodium chloride, 0; 4 per cent sodium chloride, 0·35; 8 per cent sodium chloride, 0·54. The differences were significant at the 1 per cent level. A similar relation was demonstrated between specific lysis and minimal salt tolerance. There was no effect between optimal salt concentration and specific lysis.

Envelope lysis was inhibited by calcium chloride (0·001 M) and the effect was related significantly to maximal salt tolerance (Fig. 1). No significant relation was demonstrated between inhibition by calcium chloride and either optimal or minimal salt concentration. Sodium chloride

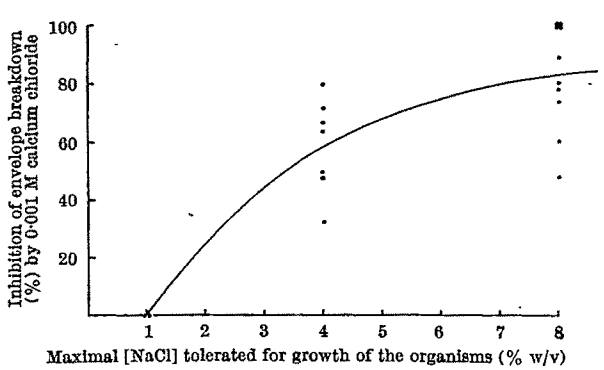

Fig. 1. Relation between inhibition of envelope breakdown by calcium chloride (0·001 M) and maximal concentration of sodium chloride tolerated during growth. Each point represents a single organism and in most cases is the mean of lysis values for two preparations. Of the four preparations with 100 per cent inhibition, two underwent slight and one extensive aggregation in the presence of 0·001 M calcium chloride. No numerical allowance has been made for this. The curve is drawn through the mean values for each group. Differences between groups were significant at the 0·1 per cent level

(0·5 M) inhibited envelope breakdown in some cases, but the extent of inhibition was unrelated to salt tolerances of the growing organisms. There was, however, a differential effect between Ca^{2+} and Na^{+}; the difference (inhibition by 0·001 M calcium chloride)—(inhibition by 0·5 M sodium chloride) showed a positive relation, significant at the 5 per cent level, with maximal salt tolerance. It is probable that the significance of the effects shown could be increased by refinements in some of the techniques used in this survey. In particular, a more realistic treatment of maximal and minimal salt tolerance rather than the present system of grouping would probably allow graphical treatment of the results. The measure, 'specific lysis', takes some account of the effect of protein content on envelope lysis, but probably not a very accurate one. In the envelope of N.C.M.B. 845 autolysis was proportional to protein in excess of about 35 per cent[3]. It is probable that a similar kind of relation exists in many of the present organisms, in which case greater accuracy would be obtained by deriving, for each organism, an envelope protein versus lysis curve.

In spite of these limitations, however, the use of simple techniques has demonstrated, within a group of Gram-negative bacteria, relations between salt tolerances of the organisms on one hand and some measures of envelope instability and cation dependence on the other. Some experimental evidence has thus been provided in support of the hypothesis that salt tolerance and membrane properties are related.

We thank Mr. A. E. Stark, C.S.I.R.O., Division of Mathematical Statistics, for the statistical analyses, and C.S.I.R.O., Division of Fisheries and Oceanography, Cronulla, Sydney, for laboratory facilities.

ENTOMOLOGY

Structure of the Brain of Insects

Insects, particularly those living gregariously, can perform very complicated activities. These activities are not less complex than those performed by higher vertebrates. It is interesting to know to what degree these activities depend on the structure of the brain. In the higher Hymenoptera the brain is relatively the most complex. The results of my investigations[1,2] show that the part of corpora pedunculata which is called 'calyx' is particularly differentiated. The walls of this calyx in the Aculeata are composed of three layers.

As has already been stressed in my previous reports, it is difficult in insects to associate a more complex structure of the brain with the ability to perform the most complicated activities. For example, the brain of termites[3] (calyx) is simpler than the brain of the higher Hymenoptera. In the walls of the calyx it is impossible to differentiate the aforementioned layers as in the case of Hymenoptera; the brain of the ant is simpler than that of the bee. In ants the third layer is scarcely visible, whereas in bees there is even a sub-layer within the third layer. Nevertheless it is impossible to state that ants and termites yield to bees as regards the performance of the manifold activities.

Both the size of the corpora pedunculata and that of the whole brain are undoubtedly of great importance here. The male of insect communities has a smaller brain than the workers. The queen of these insects also has a smaller brain in spite of its sometimes bigger body and it cannot perform such complex activities as the workers. The size of the brain of insects, as has already been reported by Goossen[4], may increase with the reduction of size of body. However, this is not correlated with increased ability of the complex activities. In this respect there is some similarity to the vertebrate brain[5,6]. That part of the brain of insects most similar to that of the vertebrate brain is the lobus olfactorius analogous to the bulbus olfactorius. There occur, however, some differences which have not been found in vertebrates—namely, those connected with sex[7]. In the lobus olfactorius of the male there occur in some parts big glomeruli which are not found in the female[8–10]. The visible differences in these refer to the glomeruli the size of which in relation to the size of brain is bigger in insects than in mammals; but the glomeruli are more numerous in mammals (Fig. 1).

When comparing the brain of insects with the brain of vertebrates, there may be observed a different structure of its most important part, the corpora pedunculata, on which the association and regulation of stimuli depend.

Some investigators comparing the brain of insects and vertebrates have attempted to make an analogy between the corpora pedunculata and cerebral cortex. Others, like Zwarzin[11], were of the opinion that a comparison is possible with the corpora striata of vertebrates. He

spring-mounted moving partition cell of Yphantis and Waugh. The concentration of enzyme remaining above the partition at the end of the run divided by the concentration in an uncentrifuged control sample (the *Q* ratio) was used in conjunction with the photograph of the meniscus and partition to calculate the radial movement of the enzyme boundary. This value was converted to an *S* value by use of an 'effective centrifugation time' at full speed (including acceleration and deceleration periods) obtained from photographs of a visible moving schlieren peak.

The enzyme produced by heterocaryon 23–39 is heat-labile and was therefore assayed by difference (before and after pre-incubation for 15 min at 43·5° C) in a mixture with wild-type enzyme centrifuged in the same cell simultaneously. The 45–48 enzyme was indistinguishable from wild in thermolability and other properties and was centrifuged separately.

Although the comparisons of two heterocaryons with the parental wild-type by the movable partition method failed to establish any differences, it was decided to compare the same and other heterocaryotic materials in density gradient tubes, since the latter method provides a much more extensive fractionation of each sample (as well as a different medium). The additional heterocaryons tested by this method were chosen because of the relatively normal properties of the adenylosuccinase they produce[3], since a general effect was being sought. Aliquots of 0·2 ml. of crude extracts were floated on a sucrose gradient in the Spinco *SW* 39 swinging bucket rotor and centrifuged at approximately 37,000 r.p.m. for 10–12 h. Samples were then collected by upward displacement with 25 per cent sucrose, in 33–35 fractions of four drops each, by means of a special tube holder with hypodermic needles at inlet and outlet.

On assay of the fractions (from either single or mixed extracts), single symmetrical bands of enzyme were found, with a width (above the half-maximal concentration level) of 5–6 fractions (15–20 per cent of the whole gradient). There was no indication of any other bands, of fractional or multiple molecular weights, nor of any significant differences among the six heterocaryons and the wild-type (74*A*) examined. No effect on sedimentation of active enzyme of wild-type or heterocaryon 45–48 was apparent after partial inactivation by heat treatment or in the presence of thioglycerol. The results are summarized in Table 2. Variation in peak position between experiments is attributable to variations in rotor speed, time, and temperature. However, such variation is compensated for by the inclusion of at least one sample from each experiment in at least one other experiment. Recovery of activity varied from 90 to 106 per cent in the partition cell, and from 70 to 100 per cent in the swinging bucket tubes, for both wild-type and mutant heterocaryon enzymes.

‡ Re origin of strains, Nos. 23, 39, 45, 48 (ref. 20). 82, 92, 103 (82, ethylmethanesulphonate; 92 and 103, nitrous acid; M. Case and N. H. Giles, unpublished).
§ Proportional to sedimentation coefficient[21].

These investigations have not provided evidence for any definite mechanism of complementation between allelic adenylosuccinase mutants. However, one possible class of mechanisms is inconsistent with the results obtained, that is, that requiring a permanent association between mutant enzyme molecules of the size normally found active in the wild-type extracts. If the heterocaryon enzymes are mixed aggregates, the active wild-type enzyme must also exist only as an aggregate of similar size, under the various conditions utilized, since there appears to be no heterogeneity in hydrodynamic properties among any or all of the active enzymes.

In a similar investigation, Braymer and Woodward[19] found evidence for heterogeneity in the sedimentation patterns of adenylosuccinase from certain *ad*-4 heterocaryons (not tested in this investigation), but not for that of wild-type or the majority of the heterocaryons. In some cases a small amount of activity was recovered from material sedimenting more slowly than the normal enzyme (personal communication). These results do not appear to be inconsistent with the foregoing conclusion.

Further evidence will be required to distinguish among complementation mechanisms involving temporary or permanent aggregation of whole molecules or parts of molecules, or retention, elimination, protection, or activation of defective portions of mutant enzymes.

We thank Dr. Mary E. Case for advice. This work was supported in part by research grants from the U.S. Atomic Energy Commission, *AT* (30-1)-872 and *AT* (30-1)-3098.

Genetic Variation of Phosphatase in Cattle Serum

A COMBINATION of starch-gel electrophoresis and histochemical staining technique was used to study a variation in the phosphatase of cattle serum. The starch-gel electrophoresis was performed as described by Gahne[1]. The starch gel was cut in three slices; the bottom slice was used for protein staining and the middle slice was stained for phosphatase in the following solution: 100 ml. acetate buffer, 0·1 M, *p*H 5·0, 100 mg sodium α-naphthyl phosphate, 100 mg *o*-aminoazotoluene diazonium salt, 10 drops

of 10 per cent solution of magnesium chloride, 10 drops of 10 per cent solution of manganese chloride, 0·5 g polyvinylpyrolidone, 2 g sodium chloride. The solution is practically the same as that used by Lawrence *et al.*[2]. The gels were incubated 16 h at room temperature. Background staining was removed by washing the gels with methanol/water/acetic acid (50 : 50 : 10). The phosphatase activity was recognized by darkly stained zones.

In some serum or plasma samples no activity of phosphatase appeared, but in other samples one or several zones were observed at the anodic side of the gel. A fast moving phosphatase fraction observed in the serum of some individuals gave rise to the most distinct zone. It was designated by the symbol *A* (Fig. 1). Its position corresponded to the α-globulin area. Two other zones appeared in the transferrin area or just in front of it. Sometimes enzyme activity was found close to the starting line and in the area between the starting line and the $S\alpha_2$-globulin.

Thus, several different zymograms were observed in different individuals. However, in investigations of 48 monozygous cattle twin pairs no differences were found within the pairs while a pronounced variation existed between pairs. In some pairs the individuals of the same pair were in different stages of pregnancy and lactation but did not differ in the enzymatic pattern. Identical zymograms including a distinct *A* zone were also found in a pair, 18 months of age, where one member was castrated as a young calf, while the other member remained intact. The zymograms of four monozygous pairs are shown in Fig. 1. The results of the studies of the monozygous twin pairs indicate a genetic basis for the variation of the cattle phosphatase.

However, the age of the tested animals has a certain influence on the enzymatic pattern. In young calves a phosphatase zone seems always to be present in the transferrin area, while the zone *A* seems to appear first in animals older than 9–10 months. These problems, as well as the nature of the phosphatase zones, will be subjected to further study. The present investigation will be restricted to the inheritance of zone *A* in animals older than one year.

The results to be presented here suggest that the variation of cattle phosphatase is determined by a genetic system symbolized by *F*, and that one allele called F^A determines the presence of the enzyme zone *A*, while another allele or alleles designated F^O give rise to zymograms without the zone *A*. The intensity of the zone *A* varies somewhat between individuals. However, it is not known whether this may be due to a difference between the homozygotes (F^A/F^A) and the heterozygotes (F^A/F^O). The symbols *A* and *O* will be used for the two phenotypic classes.

The distribution of the phosphatase types was studied in the offspring (older than one year) from 263 matings in eight herds with Swedish Red and White cattle (SRB) (Table 1). In 128 matings of the type *O* × *O* all offspring were of the type *O*. Also in the other types of matings there was a good agreement with expectancy according to the proposed genetic hypothesis.

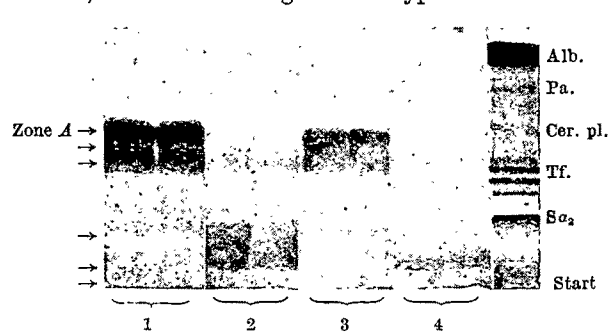

Fig. 1. Phosphatase zymograms of sera from four monozygous cattle twin pairs. Two pairs are of the type *A* (Nos. 1 and 3). Zones with enzyme activity are marked with arrows to the left. The result of amido-black staining after starch-gel electrophoresis of cattle serum of the transferrin type *A/D* and the post-albumin type *A/A* is shown to the right. Alb., albumin; Pa., post-albumin; Cer.pl., ceruloplasmin; Tf., transferrin; $S\alpha_2$, $S\alpha_2$-globulin

Table 1. Distribution of Phosphatase Types of 263 Offspring having Sire and Dam of Known Type

Phosphatase type of				No. of matings	No. of sires
Sire	Dam	Offspring			
		A	*O*		
A	*A*	14	6	20	7
A	*O*	18	18	36	
O	*A*	45	34	79	18
O	*O*	—	128	128	
Total		77	186	263	25

Table 2. Observed and Expected Number of 380 Dizygous Twin Pairs in which the Co-twins have Different or Identical Phosphatase Types

	Phosphatase types			Total
	Different	Identical		
		A	*O*	
Observed	83	57	240	380
Expected	76·0	61·0	243·0	380·0

Additional support for the genetic hypothesis was obtained in studies of 439 female cattle twin pairs. The blood samples were collected by Rendel[3] for some special purposes and the animals were randomly distributed among herds of the SRB breed. Among 380 pairs, which were older than one year and were classified as dizygous in tests for erythrocyte antigens[3], transferrins[1] and post-albumins[1], there were 83 pairs in which the members of the same pair had different phosphatase types, while 57 pairs were classified as *A* and 240 pairs as *O*. Within seven other pairs the phosphatase types differed, while the erythrocyte antigen, transferrin and post-albumin types were compatible with monozygosity. However, the morphological diagnosis indicated that these seven pairs were also dizygous.

The following gene frequencies were obtained by taking one individual at random in each twin pair, $F^A = 0{\cdot}140$ and $F^O = 0{\cdot}860$. If genetic equilibrium is supported the gene frequencies can be used to estimate the expected number of dizygous pairs in which the co-twins should have different or identical phosphatase types. The following formulæ[1] were used (p = frequency of F^A, q = frequency of F^O): (*a*) the probability that the members of a dizygous twin pair have different phosphatase types = $pq(2q^2 + 1{\cdot}5pq)$; (*b*) the probability that the members of a dizygous twin pair have both the type $O = q^2(q + \frac{1}{2}p)^2$.

The observed distribution of the female twin pairs agrees well with expectancy (Table 2).

The *A* type seems to occur in both sexes at equal frequency. A material comprising 225 SRB bulls sold at the official breed sales at an age of 18–30 months was investigated. The following gene frequencies were obtained, $F^A = 0{\cdot}133$ and $F^O = 0{\cdot}867$. These are almost exactly the same frequencies as in the random sample of female twins.

As a whole it can be concluded that the individual differences which occur in the zymograms for phosphatase in cattle seems to be under genetic control.

PSYCHOLOGY

Parameters of Electric Shock relevant to Electro-convulsion Therapy

In an earlier communication[1], I reported a finding indicating that the power dissipated in the subcutaneous tissues, where the receptors lie, is the parameter most relevant to the determination of threshold electric shocks. This led to the assertion that it would be more reasonable and safer to control wattage rather than voltage or current when using electro-convulsive therapy. As a result of correspondence with Dr. G. R. Hawkes, of the U.S. Army Medical Research and Development Command, I am persuaded that this assertion is misleading. A more accurate conclusion would have been that, although the standard practice of controlling voltage is less safe than controlling the wattage, it would probably be safer still to control current under the conditions obtaining in a mental hospital.

Two assumptions need to be borne in mind to reach this conclusion. First, by far the greater part of the impedance of a biological circuit occurs in the stratum corneum, very little being met in the subcutaneous tissues. Secondly, this impedance is a function of the nature of the contact made between the electrodes and body surface. As was pointed out in the original communication, the use of electrode jelly reduces this source of impedance to a marked extent.

Given these conditions, the relative merits of the three types of stimulation are readily compared. With a constant voltage stimulus a halving of the skin impedance virtually doubles the current. If the impedance of the subcutaneous tissues remains constant, then the power dissipated in these tissues will be quadrupled. Under constant power conditions, halving of the skin impedance produces an increased current and a reduced voltage, so that the power dissipated in the subcutaneous tissues is only doubled instead of quadrupled. With a constant current stimulus changes in the skin impedance cannot affect the power dissipated in the subcutaneous tissues, provided that the impedance of this part of the biological circuit remains unchanged.

If the skin impedance remains constant and that of the subcutaneous tissues varies, then a different picture emerges. A doubling of the impedance in the subcutaneous tissues will virtually double the power dissipated in these tissues under constant voltage, constant power, or constant current conditions, leaving little to choose between them in this respect.

All the foregoing, however, is predicated on the assumption that the impedance of the subcutaneous tissues forms an insignificant fraction of the total impedance of the biological circuit. Most evidence so far favours this assumption, although there may be special circumstances in which it does not hold. Since we know very little about the distribution of energy within a biological circuit when an external E.M.F. is applied via the intact skin a note of caution is in order. In particular, the capacitative changes that occur under these conditions are of uncertain magnitude and locus. It is, therefore, possible that with some kinds of a.c. input, and on the make-and-break with a d.c. input, there may be brief periods in which this assumption is invalidated.

If at any time the impedance of the subcutaneous tissue does form a preponderant part of the load, and if this impedance varies while skin impedance remains constant, then the constant power stimulus would provide better control of the power dissipated in the subcutaneous tissues than either a constant voltage or constant current stimulus. The odds are that these special conditions prevail less frequently when electro-convulsive therapy is being used than those conditions contingent on the two basic assumptions discussed. It follows that the patient is more likely to be safeguarded by a constant current stimulus than by a constant power stimulus, although it remains true that the constant voltage stimulus in general use is the least satisfactory of all in this respect.

If, under constant voltage conditions, electrode jelly is used either more copiously or in fresher condition in a later session of a series of electro-convulsive therapy treatments, then the voltage that was appropriate earlier in the series will be too great when the load is reduced at the skin surface. If dry electrodes are used, then the degree to which the patient is sweating will introduce a similar uncontrolled variable and expose the patient to the same danger of an unintentionally high level of shock in terms of the power dissipated in the brain.

Electrical Stimulation of Pain and Touch Systems

To take best advantage of cutaneous channels for communication, information must be translated into a form compatible with perceptual properties of the touch sense. To find whether such channels are effective other than as providing mere warning information or slow transliteration of speech, one needs systematically to vary cutaneous stimuli along temporal and spatial dimensions to determine the resolving power of the nervous system for complex patterns of cutaneous stimuli. In contrast to vibration, direct electrical stimulation of the skin has several advantages, but the disadvantage that pain ordinarily accompanies electrical stimulation of hairy body regions. The purpose of this investigation was to determine conditions of painless electrical stimulation of touch, by defining the stimulus conditions which affect pain and touch thresholds.

Touch and pain thresholds as peak current were measured in two experiments as a function of: (1) the number of brief electric pulses, from one to 20; (2) the rate of pulse repetition, 10–250 pulse/sec, on eight body regions, including hairy and hairless tissues[1]. The anodal pulses, delivered through a constant current stimulator, were 0·5 msec in duration at half-peak.

Pain thresholds were rendered relatively reliable by training procedures. One result was relaxed, attentive observers unreactive to threshold pain, in effect, a functional separation of cutaneous pain thresholds from effects of pain reaction. Also, thresholds were made stable by sufficiently long interstimulus and inter-threshold times, which minimized cumulative effects of stimulation.

Pain thresholds and touch thresholds were a decreasing hyperbolic function of the number of pulses in a stimulus train, indicating nearly linear integration of current pulses at different rates by pain and touch. Also, pain and touch thresholds fell at different rates with increasing repetition rates from < 10–100 pulses/sec. It was concluded that stimulation of touch with 0·5 msec current pulses can be reliably pain-free over much of the surface of the body given low repetition rates and low pulse number, because of the shorter time course of integration for touch than for pain.

Pain threshold current in hairy tissues was markedly different on electrode sites with high pain sensitivity relative to touch compared with those with low relative pain sensitivity; corresponding touch thresholds were nearly the same. Thus differences in the likelihood of stimulating pain on hairy tissues were primarily due to pain sensitivity differences, rather than touch sensitivity differences.

The perceptual nature of threshold pain was often described as sting on hairy tissue, dull pain on hairless regions. It was concluded that sting does not depend on the presence of hair or associated musculature, but is

related to the presence of non-myelinated free nerve endings in such tissue.

Pain thresholds in hairy tissues were raised considerably 48 h after the first session; touch thresholds were unchanged. Pain thresholds in hairless tissues were the same or somewhat lowered, thereby indicating that a general adjustment to pain does not underlie the rise. Since, in the first session, only six painful stimuli, and sometimes more than one hundred touch stimuli, were delivered to a given electrode site, pain thresholds in hairy tissue are raised solely from effects of the passage of current.

Pain thresholds on hairy tissue obtained with stimuli of varying repetition rates and pulse numbers were converted to average current per millisecond of stimulation[2]. An approximately rectangular hyperbolic relation was obtained between average current per time unit and stimulus duration, for durations as long as two seconds. Thus pain thresholds on hairy tissues are properly specified in units of average current flow and total time, not power. This finding, together with the importance of long rest intervals to sting threshold stability, points to a chemical intermediary.

Placebo Reactor

It is often believed that there exist, in the community, certain individuals who are 'placebo reactors', and that these individuals must be excluded from a controlled clinical trial if the 'true' effects of the drug in question are to be correctly assessed. Glaser[1] expressed the extreme view when he wrote "a dummy" [that is, a pharmacologically inert substance] "identifies those patients who can be disregarded, either because they need no treatment or else because they can be cured by psychological influences, and this is as reasonable a procedure as the exclusion from experiments with anti-asthmatic drugs of patients who do not have attacks of bronchial asthma".

The story of the 'placebo reactor' can largely be traced back to Jellinek[2], who reported an investigation of headache in which he found that a proportion of the sufferers obtained relief from a placebo; he further observed a U-shaped distribution of individuals, with regard to this placebo reaction, so that some 'definitely' responded while others 'definitely' did not, only very few being partially relieved. It has since been shown[3–6] that this U-shaped distribution is by no means characteristic of all drug responses, and that the incidence of placebo reactions can vary greatly with the circumstances of a trial. Nevertheless, the mythical person who 'once a placebo reactor' is 'always a placebo reactor' dies so hard that an extra nail for his coffin will perhaps do no harm.

There is, of course, no doubt that some individuals are more amenable to suggestion than others, and in a given situation this increases the likelihood of their deriving some satisfaction from a placebo[7]. Also, the cause of the symptoms is of obvious importance, as Jellinek[2] himself recognized when he wrote "the difference in response to placebo must reflect a difference in the nature of headaches". It was, indeed, a shrewd physician who said "the treatment of scarlet fever depends on what is the matter with the patient"[8].

Apart from the variability of the individual and his symptoms, the design of a drug trial may influence the number of 'placebo reactors' who are discovered, particularly in a complex situation in which several methods of grading the response to the drug are available. This is well shown in my own work on post-operative pain, with which—unlike headache—'complete relief' and 'complete non-relief' rarely occur. The design and purpose of these investigations are explained elsewhere[9]; their present interest lies in the fact that they have provided several different criteria against which 'relief of pain' may be deemed to have occurred after treatment with morphine and a placebo (normal saline).

Table 1. Incidence of 'Placebo Reactors' after Upper Abdominal Surgery

	Improvement of pain alone (%)	Improvement of pain, movement and coughing (%)	Vital capacity (%)	Peak expiratory flow rate (%)
Change of 1 grade or more = 'relief'	45	50	22	12
Change of 2 or more grades = 'relief'	0	0		

Using an arbitrary pain score, only three out of 21 of my patients failed to achieve an improvement of at least 1 grade after morphine; but if this were to be accepted as 'relief', 8 of 18 patients were relieved by saline. If an improvement of two grades was required for 'relief', no patients were relieved by saline and only 2 by morphine. Movement and coughing are especially painful after upper abdominal operations; when ability to move and cough was taken into account, an improvement of one grade or more was achieved by 19 patients after morphine (91 per cent) and by 9 after saline (50 per cent), while an improvement of two or more grades was obtained by 10 of the 21 morphine cases and by none of those who had saline. Finally, an indication of the painfulness of deep breathing and coughing was obtained objectively by measuring vital capacity and peak expiratory flow rate: the vital capacity improved in 10 of the 12 patients after morphine, and in 2 of 9 after saline; peak expiratory flow rate improved in 4 of 12 cases given morphine and in 1 of 8 given saline. Allowing for a moment that percentages can legitimately be derived from such small numbers of individuals, the incidence of patients who obtained 'relief of pain' from an injection of saline, according to these several criteria of 'relief', was as shown in Table 1.

All these figures relate only to pain after upper abdominal surgery; other types of case yielded different responses to saline. Thus, the percentage of 'placebo reactors' among my patients could be made to vary from 0 to 50 according to the stringency of my criteria of 'pain relief'. As a greater improvement is required before 'pain relief' is deemed to have occurred the number of 'placebo reactors' falls; but, at the same time, the 'effectiveness' of morphine diminishes. The investigator is at liberty to choose whether he has 'placebo reactors' or 'morphine non-reactors' among his patients.

All this makes it difficult to understand how so-called 'placebo reactors' can reliably be identified and excluded from a clinical trial, and how the 'true' effects of a drug can be dissociated from its psychological effects. In contrast to Glaser's views[1], one might observe that bronchial asthma itself not infrequently responds to psychological influences, and that "there must be something the matter with a man who comes to a doctor when there is nothing the matter with him"[10]. It is perhaps not even too much to suggest that given the appropriate circumstances each one of us has the makings of a 'placebo reactor'.

FORTHCOMING EVENTS

Tuesday, July 23—Wednesday, July 24

BRITISH SMALL ANIMALS VETERINARY ASSOCIATION AND THE UNIVERSITIES FEDERATION FOR ANIMAL WELFARE (at the Middlesex Hospital Medical School, London, W.1)—Symposium on "Anaesthesia of Small Laboratory Animals".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANTS (university graduates or holders of Diploma in Technology) IN (a) HIGH POLYMER CHEMISTRY; (b) APPLIED PHYSICS; and (c) METALLURGY—The Vice-Principal, Lanchester College of Technology, Coventry (July 25).

ANALYTICAL CHEMIST (Assistant Experimental Officer aged 18–27, with at least G.C.E. in five subjects including "A" levels in chemistry and one other subject) IN THE DEPARTMENT OF MINERALOGY for the analyses of minerals, rocks and meteorites, and research into analytical methods—The Secretary, British Museum (Natural History), Cromwell Road, London, S.W.7 (July 26).

HEAD (with good academic qualifications with teaching and/or industrial experience) OF THE ELECTRICAL ENGINEERING DEPARTMENT—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (July 26).

RESEARCH ASSISTANT (science graduate, preferably with some knowledge of genetics) to take part in a programme designed to study genetics and cytogenetics—The Secretary, Institute of Cardiology (University of London), 35 Wimpole Street, London, W.1 (July 26).

DEMONSTRATOR IN PHYSICS—The Registrar, The University, Nottingham (July 27).

LECTURER IN THE DEPARTMENT OF PHARMACOLOGY—The Secretary, The University, Edinburgh (July 27).

LECTURER (medically or non-medically qualified, with teaching and/or research experience in physical anthropology, human biology or genetics) IN PHYSICAL ANTHROPOLOGY IN THE DEPARTMENT OF ANATOMY—The Registrar, The University, Liverpool, quoting Ref. No. CV/357/N (July 27).

LECTURER OR ASSISTANT LECTURER IN CHEMISTRY (Inorganic or Physical) IN ST. SALVATOR'S COLLEGE—The Secretary, The University, College Gate, St. Andrews, Fife (July 27).

LECTURER (with a good honours degree and industrial and research or teaching experience) IN THE DEPARTMENT OF APPLIED PHYSICS to teach instrumentation and/or automatic control—The Academic Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff (July 27).

SENIOR ASSISTANT ENGINEER (Distribution Research) (with a degree in engineering or physics and wide experience of power engineering, including the design and planning of distribution systems) IN THE COMMERCIAL AND DEVELOPMENT DEPARTMENT, Headquarters in London—The Assistant Secretary (Establishments), The Electricity Council, 30 Millbank, London, S.W.1, quoting Ref. N./251 (July 27).

ASSISTANT (graduate in botany, agriculture, horticulture, or equivalent qualifications, and preferably some experience in plant pathology) TO THE MYCOLOGIST, for work involving testing the susceptibility to disease of crop varieties and at present is mainly concerned with the cereals—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (July 29).

JUNIOR LECTURER IN PHYSIOLOGY—The Registrar, Trinity College, Dublin 2, Republic of Ireland (July 29).

LECTURER (with higher qualifications) IN PSYCHIATRY IN THE DEPARTMENT OF PSYCHOLOGICAL MEDICINE—The Secretary, The University, Edinburgh (July 29).

ASSISTANT EXPERIMENTAL OFFICER (with a degree in chemistry, physics, agricultural chemistry or equivalent) to carry out chemical and physical analysis of soils—The Secretary, Rothamsted Experimental Station, Harpenden, Herts. (July 31).

BIOCHEMIST (with an honours degree) IN THE PATHOLOGY DEPARTMENT, General Hospital, Aberystwyth—The Group Secretary, Mid-Wales Hospital Management Committee, "Gorseland", North Road, Aberystwyth, Cards. (July 31).

KATHLEEN SCHLESINGER FELLOWSHIP (preferably candidate proposing to investigate degenerative diseases of the brain and central nervous system including biochemical abnormalities) tenable at the National Hospital for Diseases of the Nervous System, Queen Square, London, W.C.1—The Secretary, Medical Research Council, 20 Park Crescent, London, W.1 (July 31).

LECTURER IN MECHANICAL ENGINEERING—Head of the Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7 (July 31).

LECTURER OR ASSISTANT LECTURER (preferably prepared to lecture mainly in pure mathematics) IN MATHEMATICS—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (July 31).

LECTURER OR ASSISTANT LECTURER (with a degree in agricultural chemistry and an interest in human nutrition) IN THE DEPARTMENT OF NUTRITION—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (July 31).

LECTURER (Ph.D. standard) IN BIOPHYSICS to take part in a programme of biophysical and biological research on cilia, under the general direction of Professor Sir John Randall—The Registrar, King's College (University of London), Strand, London, W.C.2 (July 31).

SECRETARY/FIELD OFFICER (with a sound knowledge of agriculture with a background of farming experience, an agricultural college qualification or its equivalent, and preferably graduate experience of livestock breeding and genetics) to organize the Secretariat and expand the activities of the Association—The Secretary, The Sheep Development Association, Holton Paddocks, Wheatley, Oxford (July 31).

STATISTICIAN (with a good honours degree in mathematics or science and knowledge of statistical techniques as applied to agriculture or biology, but applications will be considered from students expecting to graduate in 1963) for the Agricultural Research Council's Unit of Statistics (University of Aberdeen)—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (July 31).

LECTURERS (2) IN VETERINARY CLINICAL STUDIES (Farm Animals) at the Veterinary Field Station—The Registrar, The University, Liverpool, 3 quoting Ref. No. CV/361/T (August 1).

LECTURER (with an honours degree in pharmacy or equivalent qualifications or experience, a knowledge of research methods, and preferably industrial research or production experience) IN PHARMACEUTICS—The Secretary, Royal College of Science and Technology, George Street, Glasgow, C.1 (August 2).

SENIOR LECTURERS (2) IN ANATOMY at the University of Queensland, Brisbane, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 2).

ASSISTANT EXPERIMENTAL OFFICER (with a good S.L.C., S.C.E., H.S.C., G.C.E. or equivalent or university degree) at the Royal Observatory, Edinburgh, for observational work in various fields of astronomy and astrophysics with special emphasis on galactic research—The Establishment Officer, Room 364, St. Andrew's House, Edinburgh, 1 (August 3).

ASSISTANT (with an honours degree in agricultural chemistry or biochemistry, postgraduate experience in agricultural chemistry, and preferably an interest in animal nutrition) IN THE CHEMISTRY DEPARTMENT at Auchincrulve, for advisory, investigational and teaching duties—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (August 3).

SENIOR LECTURER (with high academic and research qualifications) IN ORGANIC CHEMISTRY—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (August 6).

RESEARCH ASSISTANT (with a degree in botany, biochemistry, microbiology or genetics, and a special interest in biochemical genetics, particularly enzymology) IN THE DEPARTMENT OF BOTANY (Prof. D. Lewis)—The Secretary, University College, Gower Street, London, W.C.1 (August 9).

RESEARCH WORKER (with an honours science degree or equivalent and suitable postgraduate research experience) IN THE MEAT RESEARCH DEPARTMENT of the Animal Production Division for work on histological and histochemical aspects of muscle growth—The Director, An Foras Taluntais, 33 Merrion Road, Dublin, 4, Republic of Ireland (August 9).

ASSISTANT LECTURER (preferably honours graduate in zoology or physiology with suitable postgraduate experience) IN ANATOMY AND HISTOLOGY; and a DEMONSTRATOR (preferably honours graduate in animal husbandry or animal physiology) IN ANIMAL SCIENCE at the School of Agriculture, Sutton Bonington, near Loughborough—The Registrar, The University, Nottingham (August 10).

ANIMAL HUSBANDRY OFFICER; and an ANIMAL NUTRITION CHEMIST at the Institute of Agricultural Research, Ahmadu Bello University, Samaru, Northern Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 14).

ASSISTANT PROFESSOR IN THE DEPARTMENT OF ZOOLOGY to participate in the cell biology programme and to teach protozoology, cytology, or a related subject at the senior undergraduate level—Dr. C. V. Finnegan, Department of Zoology, The University of British Columbia, Vancouver 8, B.C., Canada (August 15).

LECTURER and an ASSISTANT LECTURER (with an honours degree in physiology or closely allied subject, and preferably some research experience) IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, The University, Edinburgh (August 15).

LECTURER IN BOTANY at Fourah Bay College, University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 18).

PROFESSOR and HEAD OF THE DEPARTMENT OF VETERINARY MEDICINE; and PROFESSOR and HEAD OF THE DEPARTMENT OF VETERINARY ANATOMY AND PHYSIOLOGY, University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 18).

PROFESSOR, SENIOR LECTURER, and a LECTURER IN THE DEPARTMENTS OF CIVIL ENGINEERING, ELECTRICAL ENGINEERING, AND MECHANICAL ENGINEERING at the University of Lagos—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 18).

SENIOR LECTURER OR LECTURER IN THE DEPARTMENT OF BACTERIOLOGY, University of Ibadan, Nigeria—The Secretary, Senate Committee on Colleges Overseas in Special Relation, Senate House, University of London, London, W.C.1 (August 19).

SENIOR LECTURER (with research experience in at least one of the basic medical sciences and familiar with modern research methodology) IN EXPERIMENTAL SURGERY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 23).

DEPUTY DIRECTOR to be head of a research section as well as carrying administrative responsibilities; HEAD OF EPIDEMIOLOGY SECTION dealing with field surveys of virus incidence, and organization and assessment of vaccine trials; and HEAD OF GENERAL VIROLOGY SECTION which includes virus-cell studies in tissue culture, viral genetics and the biophysics and biochemistry of viruses—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey (August 31).

DIRECTOR OF THE UNIVERSITY OF SHEFFIELD INSTITUTE OF EDUCATION—The Registrar, The University, Sheffield (September 7).

LECTURER OR ASSISTANT LECTURER IN PHILOSOPHY; and a LECTURER OR ASSISTANT LECTURER IN PURE OR APPLIED MATHEMATICS—The Secretary to the Trustees, Magee University College, Londonderry, Northern Ireland (September 11).

PROFESSOR OF PHYSICS in the School of Physical Sciences of the University of Adelaide at Bedford Park—The Registrar, University of Adelaide, North Terrace, Adelaide, South Australia (September 16).

CHAIR OF ADULT EDUCATION—The Registrar, The University, Manchester (September 20).

JUNIOR LECTURER (preferably qualified in education psychology and/or comparative education) IN EDUCATION—The Registrar, Trinity College, Dublin 2, Republic of Ireland (September 20).

ASSISTANT PROFESSOR or an ASSOCIATE PROFESSOR (physiologist or biochemist, M.D. and/or Ph.D.) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. M. Beznak, University of Ottawa, Ottawa, Ontario, Canada.

ASSISTANT (with special interests in inorganic or physical chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Professor, Department of Chemistry, University College, Upper Merrion Street, Dublin 2, Republic of Ireland.

BACTERIOLOGICAL ASSISTANT (with a degree in a biological subject, and preferably previous bacteriological experience) IN THE ENTERIC REFERENCE LABORATORY—The Director, Central Public Health Laboratory, Colindale Avenue, London, N.W.9.

CHAIR OF PURE MATHEMATICS—The Registrar and Secretary, The University, Bristol.

LECTURER IN BIOCHEMISTRY AND ANIMAL NUTRITION—The Bursar, Harper Adams Agricultural College, Newport, Shropshire.

LECTURER (with at least a good honours degree in chemistry, some teaching and research or industrial experience, and an active interest in research) IN INORGANIC CHEMISTRY to teach to Grad.R.I.C., B.Sc. General, and H.N.C. standards—The Principal, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

PHYSICAL OR INORGANIC CHEMIST (Ph.D., with up to five years experience) for fundamental studies in catalysis—The Director of Research, Research Council of Alberta, 87 Avenue, 114 Street, Edmonton, Alberta, Canada.

PHYSICIST and a PHYSICAL CHEMIST (of Ph.D. standing, preferably with research experience in a related field) to join a team engaged in basic long-term research into the photoconducting behaviour of organic materials—The Director, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian.

POST-DOCTORAL FELLOW for research on the biological control of glycogen metabolism (aspects involving both enzymology and metabolism are under investigation)—Dr. N. B. Madsen, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada.

POST-DOCTORAL RESEARCH FELLOW in Solid State Physics, for work on the transport and optical properties of insulating solids—The Registrar, The University, Leicester.

RESEARCH ASSISTANT (honours graduate in engineering or physics) IN ESTUARINE HYDRAULICS, to study the regime of the Clyde Estuary, with special reference to sediment movement—The Professor of Civil Engineering, Royal College of Science and Technology, George Street, Glasgow, C.1.

RESEARCH ASSISTANT (preferably with experience in cytology) to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield, 10.

RESEARCH ASSISTANT (with a Ph.D. or considerable research experience in metallurgy, physics, or chemistry) IN METALLURGY, for investigations concerned with physical and chemical reactions occurring in thin oxide films formed on surfaces of metals—Dr. J. S. Ll. Leach, Metallurgy Department, Imperial College of Science and Technology, London, S.W.7.

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (graduate in physics or physical chemistry) IN THE BIOPHYSICS DEPARTMENT, to become a member of a team investigating the structure and properties of viruses and of virus-antibody complexes—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey.

SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER (with at least a first- or good second-class honours degree with a special knowledge of entomology and preferably experience of tropical stored products problems), for research on biological problems of tropical stored products—The Director, Tropical Stored Products Centre, Pest Infestation Laboratory, London Road, Slough, Bucks.

£500 A YEAR TAX FREE

You can protect your family's future at little cost by a special plan with the Equitable. Should you die within a period of 20 years your dependants will receive £500 a year tax free for the balance of the period.
You pay premiums for only 15 years and if you are 30 now the cost is as low as £15. 15. 0. a year—about 6/- a week.
The Equitable offers attractive terms because it has no shareholders to take any part of the profits and pays no commission for the introduction of business.

TEMPERATURE!
IS THIS YOUR PROBLEM?
−100°C. TO +150°C.

★ Controlled temperature conditions are becoming more and more vital to engineering, research and national undertakings—Lec have now produced a new Low Temperature Cabinet at a price below £300 which will prove an ideal cabinet for industrial training laboratories, universities, technical and medical establishments.

★ Temperature can be pulled down to −100° F, and maintained there.

★ Lec specialize in Environment Cabinets covering a temperature range of +150° C to −100° C, combined with an altitude to 100,000 feet and humidity.

APPOINTMENTS VACANT

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Experimental Officer in the Department of Metallurgy. Duties will commence as soon as possible after October 1, 1963. The officer will be responsible for the maintenance of X-ray equipment for undergraduate teaching and for research. He will take part in the development of those research projects which rely largely upon X-ray techniques and should be able to give some service assistance to other projects. Candidates should be familiar with standard X-ray diffraction apparatus and techniques, preferably with some knowledge of counter methods, low angle scattering, fluorescence analysis, or texture determination. Some experience with electronics would be an advantage. Qualifications in physics or metallurgy are desirable—for example, graduate membership of the Institute of Physics or L.I.M. Salary range: £880 by £40 to £1,200 per annum. The initial salary will be according to qualifications and experience. Contributory superannuation scheme.

Applications should be sent not later than August 10, 1963, to the Registrar, The University, Manchester, 13, from whom further particulars and forms of application may be obtained.

UNIVERSITY OF EDINBURGH
DEPARTMENT OF PHYSIOLOGY
LECTURESHIP AND ASSISTANT LECTURESHIP

Applications are invited for the posts of Lecturer and Assistant Lecturer in the above Department. Salary scales: Lecturer, £1,250 by £105 to £1,670; bar: £1,790 by £120 to £2,150 per annum; Assistant Lecturer, £1,000 by £50 to £1,150 per annum; with placement according to qualifications and experience, and with superannuation benefit and family allowance where applicable. For both posts an honours degree in physiology or closely allied subjects is essential, and research experience is desirable. Facilities exist for research in nervous system, endocrinology and human metabolic problems, but special facilities are available for research on central nervous mechanisms concerned with vision. The successful candidates will be expected to take up duty on October 1, 1963.

Further particulars may be obtained from the undersigned, with whom applications (six copies), giving the names of two referees, should be lodged not later than August 15, 1963.

CHARLES H. STEWART,
Secretary to the University.

RESEARCH INSTITUTE (ANIMAL VIRUS DISEASES), PIRBRIGHT, SURREY, which has hitherto concentrated on foot-and-mouth disease, is extending its activities to include other animal viruses and is re-organizing research work into three or four main sections. Applications are now invited for the following posts vacant in January, 1964:

(a) Deputy Director, who will be head of a research section as well as carrying administrative responsibilities. Appointment in S.P.S.O. (£2,800 to £3,150) or D.C.S.O. (£3,275 to £3,600) grade according to age, qualifications and experience.

(b) Two posts in S.P.S.O. grade:

(i) Head of Epidemiology Section dealing with field surveys of virus incidence, and organization and assessment of vaccine trials. It also includes World Reference Laboratory on Foot-and-Mouth Disease sponsored by F.A.O. and O.I.E.

(ii) Head of General Virology Section which includes virus-cell studies in tissue culture, viral genetics and the biophysics and biochemistry of viruses.

Application form and further particulars from Secretary, to whom applications should be submitted by August 31, 1963.

Monsanto

INDIA

SALES TECHNICAL SERVICE MANAGER

RUBBER CHEMICALS

Expansion of activities in India has created the need for a rubber chemicals Sales Technical Service Manager in the Monsanto Chemicals India (Private) Ltd. organization.

Primarily the position is to create, manage, and control a rubber chemicals sales technical service laboratory. The duties will include responsibility for leading a small team of technical staff, maintaining close contact with technical developments in the rubber industry in India, and supervising the production of suitable technical literature. The position is located at Khopoli, near Bombay, and will involve some travelling.

Applications are invited from men aged up to 40 years of Indian nationality who have an honours degree in chemistry or physics obtained in a British university, or an equivalent qualification. Associateship of the Institute of the Rubber Industry will be an additional desirable qualification. A minimum of two to five years practical experience of rubber technology is essential.

The successful applicant will be a man of imagination, ambitious to take this outstanding opportunity to establish himself in India as a recognized technical expert in this field.

Excellent starting salary and career prospects, pension scheme and other benefits. Passage to India at Company's expense.

Please send details of experience, qualifications, age, etc., to:

The Staff Officer (DL 235),
Monsanto Chemicals Limited,
Monsanto House,
10/18 Victoria Street,
London, S.W.1.

Cadbury's

MATHEMATICIANS/PHYSICAL SCIENTISTS

We offer interesting work in a new section of the organisation concerned with Operational Research, the development of quality control systems, and quantitative assessment of sensory characteristics. Candidates should be under 27 years of age and have an honours degree in either Mathematics or a Physical Science. A knowledge of statistical methods would be an advantage but is not essential.

Write to :

THE EMPLOYMENT MANAGER (EMC)
CADBURY BROTHERS LIMITED,
BOURNVILLE, BIRMINGHAM

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Experimental Officer in Spectroscopy in the Department of Chemistry in the Faculty of Science. Previous experience in at least one branch of the subject is desirable. The person appointed will have the opportunity to apply a wide range of spectroscopic techniques to chemical problems. Salary range: £880 by £40 to £1,200 per annum. The initial salary will be according to qualifications and experience. Contributory superannuation scheme.

Applications should be sent not later than August 3, 1963, to the Registrar, The University, Manchester, 13, from whom further particulars and forms of application may be obtained.

POST-DOCTORAL FELLOWSHIP ($6,000, tax-free stipend) for research on the biological control of glycogen metabolism. Aspects involving both enzymology and metabolism are under investigation.—Apply Dr. N. B. Madsen, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada.

UNIVERSITY OF SHEFFIELD

Applications are invited for a post of Research Assistant to take part in a programme designed to study human chromosome abnormalities and associated disorders. Experience in cytology desirable, but not essential. Suitable for candidates graduating this year. Salary £700 to £900 per annum, according to qualifications and experience.

Further details available from the Secretary, Genetics Department, the University, Sheffield, 10.

GRADUATE OR PERSON QUALIFIED OR experienced in the rubber and/or plastics field required in the Information Division of the Rubber and Plastics Research Association of Great Britain for abstracting scientific literature and answering technical inquiries. Salary according to age and experience within the range £620 to £1,075. Five-day week. Canteen.—Apply in writing to Secretary, R.A.P.R.A., Shawbury, Shrewsbury, Shropshire.

PRODUCT DEVELOPMENT METALLURGIST

The Electrolytic Zinc Company of Australasia Limited have a vacancy for a Senior Physical Metallurgist at their Works at Risdon, near Hobart, Tasmania.

The Company is extending its activities in the fields of product development and technical service with particular reference to present and potential uses of zinc, zinc alloys and zinc products. The successful applicant will be required to take part in and supervise the research and development aspects of this work. He will be expected to initiate investigations into new uses for zinc as well as implement programmes for improvement of existing applications.

QUALIFICATIONS: Applicants should preferably have a University training in physical metallurgy, and some years of experience in metallurgy—either in research or production. They should be capable of supervising metallurgical research, both fundamental and applied.

Appointment is subject to medical examination including chest X-ray.

SALARY: Will be dependent on qualifications and experience and will be at a rate of up to £A3,000 per annum. In addition, a discretionary bonus scheme is in operation based on the prosperity of the Company.

BENEFITS: A Staff Provident Fund is available to which the Company subscribes three-quarters of the contribution.

Contributory Hospital and Medical Benefit Schemes are operated by the Company and Dental Treatment is available at a nominal charge after completion of one year's service.

Accommodation can be made available for a married applicant on a rental basis if required. Assistance can be given to single men in finding accommodation.

REMOVAL EXPENSES: Fares and travelling expenses will be paid for the successful applicant and his family. A liberal contribution will also be paid towards the cost of transporting personal effects.

APPLICATIONS: Should contain full details of courses studied, results obtained, and of subsequent experience and should include the names of at least two referees. They should be forwarded to:

The General Superintendent,
Electrolytic Zinc Co. of A/asia Ltd.,
G.P.O. Box 377-D,
HOBART, Tasmania.

UNIVERSITY OF LAGOS MEDICAL SCHOOL

Applications are invited for (a) Lectureship or (b) Junior Lectureship or Junior Research Fellowship in Pharmacology in Department of Physiological Sciences. Candidates should have a higher degree, with some teaching and research experience. Medical qualification desirable but not essential. Appointment to commence October 1, 1963, or as soon thereafter as possible. Salary scales: (a) £2,200 by £100 to £2,600 per annum; (b) £1,200 by £100 to £1,700. Entry point depending on qualifications and experience. Passages for appointee, wife and up to five children under 11 years on appointment, leave, and termination. Children's and car allowances. Superannuation scheme. Part-furnished accommodation at rent not exceeding 7 per cent of salary. Free medical attention.

Detailed applications (six copies), naming three referees, by August 15, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF CAMBRIDGE

Applications are invited for a Senior Assistantship in Research in Causal Morphology and Fine Structure in the Department of Botany, from October 1, 1963. Candidates should have experience of the application of electron microscopy to plant material. Pensionable stipend in scale £1,250 by £60 to £1,670, plus children's allowance.

Further particulars from Dr. H. L. K. Whitehouse, Botany School, Downing Street, Cambridge. Closing date for applications: August 31, 1963.

THE AGRICULTURAL RESEARCH COUNCIL require an Assistant Experimental Officer at their Ditton Laboratory for work of essentially practical nature on the storage and handling of potatoes. Applicants should have a pass degree in agriculture and an interest in applied research. Salary according to age in scale £590 at age 20, £858 at age 26 or over, rising to £1,053. The post entails considerable travelling.—Forms of application may be obtained from the Secretary, Ditton Laboratory, Larkfield, nr. Maidstone.

Monsanto

RESEARCH CHEMICAL ENGINEER

Monsanto Chemicals Limited require a Research Chemical Engineer with an interest in reaction kinetics to work on chemical engineering aspects of high pressure polymerization reactions. This work will be carried out in our research establishment at Fawley, Hampshire, on the edge of the New Forest.

Applicants should have a good honours degree in chemical engineering with post-graduate or industrial research experience.

Good starting salary and career prospects, non-contributory pension scheme.

Please send applications, giving details of age, education, and previous experience to:

The Staff Officer (DL 236),
Monsanto Chemicals Limited,
Monsanto House,
10/18 Victoria Street,
London, S.W.1.

MEDICAL RESEARCH COUNCIL

LABORATORY OF MOLECULAR BIOLOGY

A vacancy exists for a Graduate in Physics with experience of biological materials, or in a biological science with experience of physical methods, and at least two or three years of postgraduate work, to join small group, under Dr. H. E. Huxley, F.R.S., working on the mechanism of muscular contraction, and to assist in low-angle X-ray diffraction studies of muscle and muscle proteins. Experience with X-ray diffraction work advantageous but general experimental ability more important. Salary scale: £850 to £1,050 or £1,150 to £1,350 according to experience and qualifications.—Applications, giving the names of two referees, should be addressed to Dr. H. E. Huxley, F.R.S., Medical Research Council's Laboratory of Molecular Biology, Cambridge.

UNIVERSITY OF MANCHESTER

Applications are invited for the posts of Lecturer and Assistant Lecturer in the Mechanics of Fluids in the Faculty of Science. Applicants, who will be required to teach Mathematics and Aeronautical Engineering students, may have special qualifications in any branch of fluid mechanics or aerodynamics, but one post may be filled by an applicant with special interests in low speed fluid mechanics and aeroelasticity. The salary scales are as follows: Lecturer, £1,250 to £2,150 per annum; Assistant Lecturer, £1,000 to £1,150 per annum. Membership of F.S.S.U. and Children's Allowance Scheme. Status and initial salary (at the grade of Lecturer) would depend upon qualifications and experience.

Applications should be sent not later than August 15, 1963, to the Registrar, the University, Manchester, 13, from whom further particulars and forms of application may be obtained.

ROTHAMSTED EXPERIMENTAL STATION

HARPENDEN, HERTS

Assistant Experimental Officer to carry out chemical and physical analysis of soils. Degree in chemistry, physics, agricultural chemistry or equivalent. Starting salary between £641 (age 21) and £858 (age 26 or over) on scale rising to £1,053. Superannuation.

Applications, naming two referees, to the Secretary by July 31.

RESEARCH INSTITUTE (ANIMAL VIRUS Diseases), Pirbright, Surrey, invites applications from graduates in physics or physical chemistry for a post in the Biophysics Department. The successful applicant will become a member of a team investigating the structure and properties of viruses and of virus-antibody complexes. The work involves studies by a variety of physical methods (X-irradiation, electron microscopy, ultracentrifugation, etc.) and biological assay procedures. A suitably qualified candidate could work for a higher degree. Appointment in Scientific Officer Grade, £791 to £1,309, or Senior Scientific Officer Grade, £1,438 to £1,772. Starting salary depending on age, experience and qualifications. House available for married man. Superannuation under F.S.S.U.—Applications to Secretary.

WELSH COLLEGE OF ADVANCED TECHNOLOGY

DEPARTMENT OF APPLIED PHYSICS

Applications are invited for a post as Lecturer to teach Instrumentation and/or Automatic Control in the above Department. The appointment will be from September 1, 1963, or as soon as possible thereafter. Applicants should have a good honours degree and industrial and research or teaching experience. The person appointed must be able to plan and organize undergraduate courses in Instrument Technology and/or Automatic Control, in particular for students in the final year of the Dip.Tech. Course in Applied Physics and later at postgraduate level. Successful candidates will be expected to pursue some research or development project and every encouragement and assistance will be given to this end. Salary scale: £1,600 by £40 to £1,800 (under review by the National Incomes Commission).

Further particulars and application forms, to be returned by July 27, 1963, quoting reference number 176 BC, may be obtained from the Academic Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff.

D.S.I.R.

NATIONAL PHYSICAL LABORATORY, TEDDINGTON, MIDDX.

Senior Scientific Officer/Scientific Officer Physicist with an interest in Radiation Dosimetry is needed. After an initial period of training in existing work and techniques involved, research would be undertaken to extend the existing energy range of absolute dose measurement, to include very high energy X- or gamma-radiation, and electrons, using microcalorimetry as well as ionization methods. Qualifications: first- or second-class honours degree in physics or equivalent; for the senior post at least three years' post-graduate research experience is required together with evidence of originality. Salary: Scientific Officer, £831 to £1,359; Senior Scientific Officer, £1,488 to £1,832.

Application form from Director at above address, quoting **120XY**. Closing date August 6, 1963. (5)

UNIVERSITY OF THE WEST INDIES

Applications are invited for Senior Lectureship in Microbiology. Duties include instruction in microbiology for students working for medical degrees of London University and routine clinical microbiological work for University College Hospital. An appointment on secondment would be considered. Salary scale: £2,400 by £100 to £3,400 per annum. Child allowance £150 per annum first child, £100 per annum second, £50 per annum third. F.S.S.U. Housing allowance of 10 per cent of salary, or, if available, unfurnished accommodation will be let by University at 10 per cent of salary. Up to five full passages on appointment, on normal termination, and on triennial study leave.

Detailed applications (10 copies), naming three referees, by August 7, 1963, to Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1, from whom further particulars may be obtained.

GLASGOW ROYAL INFIRMARY

PULMONARY PHYSIOLOGIST

Graduate with honours in physiology with interest in respiratory physiology, and with experience of pulmonary function techniques desirable, but not essential, required for Pulmonary Function Unit now being established. Salary at Hospital Service rate according to experience.

Apply in writing, giving two names for reference, and not later than August 15, 1963, to the Secretary, Glasgow Royal Infirmary, 84 Castle Street, Glasgow, C.4.

UNIVERSITY OF LANCASTER

The University invites applications for a CHAIR OF PHYSICS (other than nuclear physics).

Applications (10 copies), naming at least two referees, should be sent before October 12, 1963, to the Secretary of the University, P.O. Box 78, County Hall, Preston, from whom further particulars may be obtained.

UNIVERSITY OF IBADAN

NIGERIA

Applications are invited for post of Photocopy Technician to work under direction of Senior Technician in University Library microfilm and photocopying section. Good experience in processing and dark-room work, maintenance of equipment and knowledge of processes of documentary reproduction desirable. This is a training post and candidates will be judged on their suitability and willingness to be further trained in appropriate techniques, management of a library photocopying service and maintenance work. Salary scale: £950 by £25 to £1,050 per annum. Passages paid for appointee, wife and up to five children under 11 years, on appointment, approved overseas leave and termination where applicable. Children's and car allowances. Pension scheme. Part-furnished accommodation at rent not exceeding 7 per cent of salary.

Detailed applications (six copies), naming three referees, by August 14, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

AMENDED ADVERTISEMENT

UNIVERSITY COLLEGE OF RHODESIA AND NYASALAND

Applications are invited for three posts of (a) Senior Lecturer, or (b) Lecturer, or (c) Assistant Lecturer in Physics, for one of which applicants should have strong qualifications in geophysics. Appointments on secondment would be considered. Salary scales: (a) £2,100 by £100 to £2,600 per annum; (b) Grade 1, £1,880 by £80 to £2,200 per annum; Grade 2, £1,450 by £70 to £1,800 per annum; (c) £1,200 by £50 to £1,350 per annum. Passages to Salisbury for appointee, wife and dependent children on appointment, with allowance for transport of effects. Installation grant of £100 for persons recruited from outside Africa. Superannuation and medical aid schemes. Unfurnished accommodation at rent of 15 per cent of salary. Assistance given for triennial visits overseas.

Detailed applications (six copies), naming three referees, by August 8, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

GOVERNMENT OF UGANDA

Biochemist required to be in charge of the Biochemistry Division of the Laboratory services located in Kampala and serving all parts of the country and all races. Most of the work originates from Mulago Hospital. Excellent library facilities and opportunities for research. Candidates should possess an honours degree in chemistry, be Associates of Royal Institute of Chemistry and have at least two years postgraduate experience in medical biochemistry. They must also be nationals of and permanently resident in Great Britain or the Republic of Ireland. Appointment on contract for one tour of 21-27 months. Salary between £1,221 to £2,448 a year according to qualifications and experience. Gratuity, taxable, of 25 per cent of total emoluments on satisfactory completion of contract. Education allowances at varying rates. Mid-tour passages for children in U.K. and for whom education allowance is being paid. Quarters with heavy furniture available at a rental not exceeding £102 a year. Return passages for officer, wife and dependent children. Approximately four months' home leave on full pay or total gratuity of 45 per cent on satisfactory completion of contract. Local leave of 16 days a tour.

Further information and application forms from the Director of Recruitment, Department of Technical Co-operation, 3 Sanctuary Buildings, Great Smith Street, London, S.W.1. (Please state full name and quote RC 205/153/026.)

UNIVERSITY OF LONDON KING'S COLLEGE

DEPARTMENT OF BIOPHYSICS

Applications are invited from candidates of Ph.D. standard for the post of Lecturer in Biophysics. The successful applicant will be expected to take part in a programme of biophysical and biological research on cilia, under the general direction of Professor Sir John Randall.

Salary according to age and experience within the scale £1,250 by £60 per annum to £1,670 then by £80 per annum to £1,830; then subject to review by £80 to £2,150. A London allowance of £60, family allowances and F.S.S.U. benefits will also be payable.

Applications, giving full details of experience, should reach the Registrar, King's College London, Strand, W.C.2, not later than July 31

PILKINGTON BROTHERS LIMITED

Glass Manufacturers, require

A PHYSICIST

at their new Lathom Research Laboratories for problems covering basic research work and its application to process plant.

Theoretical and experimental work in fluid dynamics would include model studies in viscous and non-viscous flow, heat transfer in high temperature furnaces; and the design and analysis of experiments at small-scale and pilot-plant level for which a knowledge of statistics would be useful.

The requirements are: age about 30 years, with a good honours degree in Physics and some experience of a high temperature process industry.

Please quote RES./M3 in replying to L. P. Laidlaw, Group Staff Department, Pilkington Brothers Limited, Grove Street, St. Helens, Lancashire.

THE ROYAL COLLEGE

NAIROBI

Applications are invited for Senior Research Fellowship in Parasitology in Department of Zoology. Candidates should have a Ph.D. or equivalent postgraduate research experience and should give an outline of the research they would prefer to pursue. Appointment for three years. Salary £1,350 per annum. F.S.S.U. medical scheme. Subsidized accommodation. Return passage to Nairobi for appointee. Baggage allowance.

Detailed applications (six copies), naming three referees, by August 18, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

ROWETT RESEARCH INSTITUTE

(ANIMAL NUTRITION AND ALLIED SCIENCES)

Biochemist or Chemist for Lipids Biochemistry Department. Salary scales: Scientific Officer/Senior Scientific Officer £791 to £1,309 or £1,438 to £1,772, with placing according to age and experience. Superannuation F.S.S.U. Qualifications: good honours degree, or its equivalent, and research experience.

Apply with fullest particulars by August 15, naming three referees, to the Secretary of the Institute, Bucksburn, Aberdeen.

WELSH NATIONAL SCHOOL OF MEDICINE

(UNIVERSITY OF WALES)

APPOINTMENT OF TRAINEE BIOCHEMIST

Applications are invited for the above appointment. The post is intended for a person having a degree or equivalent qualification in chemistry, with experience in or wishing to take up clinical biochemistry. Salary within the scale £720 to £1,020 per annum; point of entry according to qualifications and experience. Pension scheme.

Applications, in writing, within three weeks of the appearance of this advertisement, to the Professor of Pathology, Cardiff Royal Infirmary, from whom further information may be obtained.

UNIVERSITY OF LAGOS MEDICAL SCHOOL

Applications are invited for Associate Professorships in Virology and Bacteriology (two posts) in Department of Microbiology. Candidates must have postgraduate qualifications and considerable experience in the speciality. Medical qualifications advantageous. Duties include teaching and clinical and research work. Appointments carry honorary consultantships to Lagos University Teaching Hospital. Preference given to candidates with experience in teaching hospitals. Appointments to commence October 1, 1963, or as soon thereafter as possible. Salary £3,200 per annum. Passages for appointee, wife and up to five children under 11 years on appointment, leave and termination. Children's and car allowances. Superannuation scheme. Part-furnished accommodation at rent not exceeding 7 per cent of salary. Free medical attention.

Detailed applications (eight copies), naming three referees, by August 15, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY COLLEGE OF RHODESIA AND NYASALAND

Applications are invited for post of Chief Technician in Zoology Department from candidates with university or equivalent experience. Salary scale: £1,200 by £100 to £1,700 per annum, entry point depending on qualifications and experience. Superannuation and medical aid schemes. Passages to Salisbury for appointee, wife and dependent children on appointment, with allowance for transport of effects. Installation grant of £100 in addition for persons recruited from outside Africa.

Detailed applications (six copies), naming three referees, by August 13, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF IFE

NIGERIA

Applications are invited for (a) Senior Lectureships, (b) Lectureships, or (c) Assistant Lectureships in: (i) Animal Nutrition; (ii) Animal Breeding and Genetics; (iii) Animal Health (registrable veterinary qualifications essential); (iv) Soil Microbiology; (v) Tree and Economic Crop Agronomy. Salary scales: (a) £2,275 by £75 to £2,575 per annum; (b) £1,200 by £75 to £1,650/£1,725 by £75 to £2,175 per annum; (c) £950 by £50 to £1,100 per annum (or if over 28 or holding a higher degree £1,050 by £50 to £1,150 per annum). Initial appointments three years, to commence as soon as possible. Secondment for a period of not less than one (but preferably two) academic sessions considered. Passages for appointee, wife and up to five children on appointment, leave and termination. Children's, car, and outfit allowances. Superannuation scheme. Part-furnished accommodation.

Detailed applications (eight copies), naming three referees, by August 10, 1963, to Secretary, Inter-University Council for Higher Education Overseas, 20 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

MONASH UNIVERSITY

VICTORIA, AUSTRALIA

Applications are invited for appointment to the following positions: (a) Reader or Senior Lecturer in Microbiology; (b) Lecturer in Microbiology. Applicants should be free to take up duty in December, 1963, or January, 1964. The Department of Microbiology will be accommodated in newly built and equipped laboratories at the Monash University Medical School, Alfred Hospital. Undergraduate teaching in microbiology for the M.B., B.S. degree starts early in 1964. Research interests of the department will be concerned mainly with viruses and organisms in the borderland between viruses and bacteria. Further information about the department and its research programme may be obtained from Professor B. P. Marmion. Salary ranges: Reader, £A3,000 to £A3,300 per annum; Reader (if medically qualified), £A3,100 to £A3,400 per annum; Senior Lecturer, £A2,480 to £A3,000 per annum; Senior Lecturer (if medically qualified), £A2,600 to £A3,300 per annum; Lecturer, £A1,660 to £A2,450 per annum, with superannuation on the F.S.S.U. basis.

Information regarding application procedure, conditions of appointment, superannuation, travel and removal allowances, study leave and housing, is available from the Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the University, P.O. Box 92, Clayton, Victoria, Australia. Closing date: Applications close in Australia and London on August 30, 1963.

FIELD STUDIES IN EDUCATION

IN 1960 the Nature Conservancy set up a strong Study Group under the chairmanship of E. M. Nicholson to examine the role of field studies in education. The investigations of the Group were extensive, the work of many hands, so that the report, which has now been published, will serve to mould and to crystallize opinion for some time to come*.

In the report, field studies are taken as comprising the out-of-doors aspects of biology and the earth sciences, geology and geography; and while in the discussion activities of students at field centres occupy a central place, consideration is given to the educational needs of children of any school age, members of youth organizations and, to a lesser degree, the public at large. In almost all respects the Group finds that present facilities fall seriously short of requirements; however, it is expecting a big drive forward in the next few years, associated with reforms in biology teaching which are now in train. Looking on the present situation as fluid and dynamic, the Group invites the co-operation of all people who have constructive proposals to offer. It is in this sense that the following comments are made.

The Group is at its best in presenting a comprehensive survey of facilities for field studies which are now available. It is less convincing in discussing their educational mission. It is a minor point that it makes no reference to the personal observation of the weather, of the expanse of the night sky viewed away from the lights and bustle of the towns, and of the experience of being alone with Nature between dusk and dawn.

More seriously, the Group assumes that children possess a special, innate curiosity about living things and that field studies should serve as a gateway to science. These assumptions are open to question. Altogether, the waxing and waning of interest in things at different stages of life deserve more attention than they have so far received. By the age of fifteen, most boys and girls feel that primroses and blackbirds count for little in their lives, yet at later ages they may become keen about flower gardening. That is why the teaching of natural history below the grammar school needs to be based on individual interest, for in the time available instruction in health and human physiology has more cogent priority.

Love of Nature is a complex emotion, sometimes imbued with patriotism. As the report shows, the organized study of wildlife in Holland is meagre; all the same, public support for conservation is massive, and in intensity of culture. Dutch farming is about the best in the world. Besides, in these days, evidence for the evolutionary origin and unity of all living matter has acquired such compelling validity that it provides grounds for our own reaction to Nature which, rising above æsthetic satisfaction, may attain to reverence of a spiritual kind.

In relation to field studies, as the report shows, the Forestry Commission is helping. However, it might well do much more, for besides possessing large areas of almost unspoiled country, the Commission could provide students with some comprehension of how in certain sectors biological science is being developed and applied. This is truer still of agriculture, in which context the work of the Association of Agriculture has been overlooked. Farming, for example, can present exemplifications of soil science, plant and animal nutrition, genetics, etc., which find little counterpart in the wild. Along these lines, agricultural colleges and farm institutes could be put to more imaginative use, and the National Agricultural Advisory Service is well placed for taking on a more educational role. For comparable reasons, efforts should be made to give some biology students at first hand a better understanding of the life and economic resources of the seas.

In the teaching of biology at all levels, emphasis on finding out will have been pressed too far if it prevents students from gaining some knowledge of the ways in which the application of science contributes to the welfare and culture of man. Of this, medicine is a striking example. Among sixth-form biologists attending field centres, would-be doctors probably make up the largest contingent. There is next to no flow of training in the reverse direction. In other words, the time has arrived when thought should be given to the expansion of field studies into a wider range, and then integrated with a still greater educational whole.

* *Science Out of Doors: Report of the Study Group on Education and Field Biology.* Pp. xvi+240. (London: Longmans, Green and Co., Ltd., 1963.) 12*s.* 6*d.*

FROM ELECTROMAGNETIC WAVES TO CHROMATOGRAPHIC PEAKS

Comprehensive Biochemistry

Edited by Prof. Marcel Florkin and Prof. Elmer H. Stotz. Vol. 1 : Atomic and Molecular Structure. Pp. xi+253. 62*s.* Vol. 3 : Methods for the Study of Molecules. Pp. xiii+324. 80*s.* Vol. 4 : Separation Methods. Pp. xiii+282. 70*s.* (Amsterdam and New York : Elsevier Publishing Company, 1962.)

IF it is becoming necessary for the editorship, let alone the authorship, of a scientific treatise to be shared, it is surely presumptuous for one person to assume the role of critic. It is therefore with hesitation and humility that I attempt to survey the remaining three volumes of Section 1 of *Comprehensive Biochemistry*.

One's first impression is of a disciplined economy of style by an eminent and international team of authors. Volume 1 opens with accounts by W. Parker Alford and H. H. Jaffé of the modern concepts of atomic structure and valency, which, although not exhaustive, probably contain as much as the average biochemist has the time or will to absorb. The reader may find it advantageous to read two short chapters by G. J. Bullen at the beginning of Volume 3 before embarking on the long chapter by J. D. Bernal on the structure of molecules in Volume 1. It is curious that the editors should have considered it desirable to discuss molecular structure before dealing with crystallography and X-ray diffraction methods. Even the last-mentioned two topics could have been brought together in a single chapter. Fortunately, there are a number of cross-references. J. D. Bernal's chapter is divided into two main sections. The first deals with the general features of molecular structure, such as the types of interatomic forces which operate between non-convalently bound atoms, the classification of molecular shapes, and the physical properties of polymer aggregates. The second section considers biochemical molecules from simple amino-acids to proteins and nucleic acids. There is a short section on cellular structure, but the technique of electron microscopy is not described, although it receives passing mention in

Volume 3. There are two unfortunate features of this chapter. Unlike the other chapters in these volumes, which each concludes with a bibliographical section, references here are found partly in the text and partly in tables. Conformity of style would have been appreciated by the reader. Secondly, diagrams 2(*b*) and 2(*d*) (pp. 118–9), which illustrate early stages of the elucidation of the structure of vitamin B_{12} when the presence of a porphyrin ring-system was suspected, should have been omitted or adequately explained. They are rather misleading as they are presented. The final chapter of Volume 1 contains a good but very condensed account of stereoisomerism by K. Mislow.

In Volume 3, following the two chapters by Bullen mentioned here, attention is mainly directed towards the use of spectral methods of determining structure. The absence of any discussion of mass spectrometry is noted with regret. N. H. Nachtrieb briefly describes the technique of emission spectroscopy as applied to metal analysis in biological material. R. A. Morton gives a much longer account of spectrophotometry in the ultra-violet and visible regions. To some extent this chapter is coloured by Morton's own special interests in carotenoids, vitamin A and the visual pigments; it is a pity that room was not found for newer fields such as the use of difference spectra for the study of the conformation and denaturation of proteins. On the other hand, the details for checking and calibrating a spectrophotometer are welcome. There follows a chapter on infra-red spectroscopy by L. J. Bellamy, which is deliberately slanted for the biochemist. There is practically no theoretical treatment, and the cited examples of the use of infra-red spectroscopy are carefully selected to encourage its wider use in biochemical laboratories. A short, clear account of fluorescence, including quenching and polarization, and phosphorescence is given by A. Ehrenberg and H. Theorell; this chapter includes a brief explanation of singlet and triplet states and their relation to absorption and emission of radiation. Two chapters on electron paramagnetic (S. I. Weissman) and nuclear magnetic resonance (C. D. Jardetzky and O. Jardetzky) complete the spectroscopic section of Volume 3. The final chapter, by C. Sadron and M. Daune, on the behaviour of macromolecules in solution reveals another example of the curious arrangement of the subject-matter of these volumes. It is complementary to the two chapters by W. D. Stein in Volume 2 and should have followed them.

Volume 4 is devoted to separation methods, and opens with a chapter by L. C. Craig on countercurrent distribution. This chapter is good so far as it goes; but one is left wondering why steady-state distribution was omitted, particularly now that commercial equipment is available. There follows a long discourse on chromatography by E. Lederer and M. Lederer; much of this is a précis of their well-known text-book and now looks rather *passé*. Far too much space is devoted to adsorption chromatography; too many 'gimmicks', which never became popular, are given another airing; important new techniques such as thin-layer chromatography, gel filtration, the use of ion-exchange derivatives of cellulose and dextrins are either not mentioned or given inadequate coverage. The final chapter by P. Chovin, on gas chromatography, starts with 3 pages of symbols and ends with 1½ pages of applications of the technique, a treatment that is not likely to win any newcomers to this type of chromatography.

To summarize, the first section of *Comprehensive Biochemistry* will satisfy to a large extent the long-felt need for a fundamental treatise of biochemistry, but it could have benefited from better planning by editors and authors alike. The magnitude of the task, the need for rapid publication and the multi-national composition of the contributors are difficulties which should not be underestimated, but then neither should the price.

D. T. Elmore

ADVANCES IN VETERINARY SCIENCE

The Veterinary Annual, 1962

Edited by W. A. Pool. Fourth Year. Pp. xx+419+24 plates. (Bristol: John Wright and Sons, Ltd., 1963.) 45*s*.

THIS is the fourth year of the attempts made by the editor to gather together into one volume some account of the advances made in veterinary science. Veterinary science is a vast subject and many allied disciplines impinge on it. With the help of about 35 men and women drawn from veterinary schools, research institutes and Government departments this fourth *Annual* is published. Within the past couple of years the editor has included special articles which, according to his introduction, are chosen for various reasons. They may show the outlook in a particular country, a particular type of veterinary activity, or the outlook on an advanced type of research on a subject of general importance.

Actinomycosis has been selected this year for special consideration; it is written by a surgeon, and there is apparently little new knowledge on this subject available. The other special articles deal with problems on animal breeding, with cattle practice in England, with foot-and-mouth disease in the Americas, with the impact of ornithology on veterinary practice and research, and with some statistical information. Three deal with related matters; one with veterinary affairs in Africa south of the Sahara, another with veterinary education in underdeveloped countries, and the third with veterinary services in inland Australia. These are not confined to factual accounts and the personal views of the authors emerge; there is a common factor and that concerns the necessity for an improvement in methods of animal husbandry if the hungry people of the world are to be fed an adequate amount of protein. The problems come within the province of the veterinary surgeon, for animals cannot be raised or maintained economically unless they are healthy and free from disorders associated with infection and with nutritional, genetic and environmental errors.

About three-quarters of the *Annual* is given to reviews of present literature. Unfortunately the space granted to each section and sub-section precludes adequate reviews. Veterinary physiology takes about five and a half pages, and one of them is concerned with a list of references. These lists of references are most valuable for they are nearly all recent ones and concern papers published for the most part during 1961. It is not possible to review a subject in which there are 50–60 references and a little over four pages of text. This is a general criticism for, whether the authors are considering the recent advances in diseases related to infective agents, to nutritional, metabolic and reproductive disorders, to public health or to relevant legal decisions and legislation, the list of references is long and extensive and the criticism meagre.

In addition to an index there are two brief sections devoted to new drugs and appliances and to new publications. The short descriptions of the new drugs and appliances have been derived from information supplied by the makers and the maker's name and address are appended. The list of English veterinary works and new editions published during the preceding year contains popular and scientific books and pamphlets.

The editor is courageous and persistent in his yearly attempts to include into about 400 pages so much on such a wide field. It is questionable whether these efforts are a success; the publication of the fourth *Annual* suggests that it is worth while. On the other hand, there is a danger that the uninitiated may be guided along unusual and dangerous paths by directing attention too closely to the text displayed. The book is too short to be critical when consideration is given to the amount and size of the field of relevant knowledge. The special articles are interesting if read with a critical mind. The lists of

references are useful for the research worker who wants a lead to the literature and will not be content unless he reads the original contributions. The veterinary surgeon in practice will, if selective, obtain help. To each reader and user of the *Annual* there is the warning of the need for caution and care. R. LOVELL

ANALYSIS OF ANIMAL ECOLOGY

Animal Ecology

Aims and Methods. By A. Macfadyen. Second edition. Pp. xxiv+344+6 plates. (London: Sir Isaac Pitman and Sons, Ltd., 1963.) 42*s*. net.

THE old days when ecology was largely descriptive seem far away. Because of modern advances in techniques and methods of analysis, animal ecology is now in a very interesting stage of development, which makes a general ecological synthesis by no means an easy task at the present time. Field workers are slowly elaborating specialized methods for the investigation of different classes of problems and tend to get deeply immersed in these technicalities so that it is hard for them to take a broad view of the whole subject the methods of analysis of which and even methods of thought are at present so diverse.

In *Animal Ecology: Aims and Methods*, Mr. Macfadyen has made a very interesting and valuable survey of ecological methods. He is a specialist in the investigation of the fauna of the soil and has made considerable advances in the understanding of energy relationships. These aspects of ecology were emphasized in his successful book of 1957 and the present book is an enlarged and extensively revised second edition. Within the limits of a moderate-sized book full coverage of all aspects of ecology cannot be expected and this is a selective rather than a comprehensive work. Although some examples are quoted from freshwater and marine investigations and chosen papers on mammals, birds, fishes and invertebrates are reported and discussed, the emphasis lies quite firmly on the terrestrial ecology of temperate regions. Tropical ecology is virtually omitted. The work of the large teams of agricultural and medical entomologists investigating the ecology of locusts, tsetse flies and mosquitoes gets almost no mention. However, the emphasis on temperate terrestrial ecology is an important reason for the book's popularity with British and North American students who can use it in connexion with class exercises.

The first part of the book deals with the ecology of individuals and relates the animal to its physical, plant and animal environment. There is a chapter on distribution (but migration is scarcely mentioned) and one on animal metabolism. The second part of the book is on single species populations. Here the reader is introduced to collecting methods and the estimation of animal numbers, demography, population regulation and the biomass and metabolism of populations. The third part, on the ecology of animal communities, occupies half the book and is divided into seven chapters of which the largest is on the application of population dynamics. Here the author selects a dozen miscellaneous ecological investigations, provides a detailed report on each and discusses their general significance in relation to theories of population regulation. One could have wished for a rather more critical approach here, because the author has not reduced all his examples to a common system of terminology and concept and some confusion in their interpretation remains.

Unfortunately the book is marred by a few errors, which have slipped through unchanged from the first edition, such as the minus sign in the equation on p. 70, and the misleading statement about the advantages of saturation deficit as a method of expressing atmospheric humidity. One also regrets the needlessly restrictive definition of K as a population *maximum* on p.133. Had it been defined as an *equilibrium* population which in fact it is, the arguments about population change which follow could have been far more logically stated. These defects are minor ones and the book can be recommended as probably the most useful modern text of ecology for its size.

G. C. VARLEY

LEARNING BEHAVIOUR IN ANIMALS

Learning and Instinct in Animals

By Dr. W. H. Thorpe. Second edition. Pp. x+558. (London: Methuen and Co., Ltd., 1963.) 63*s*. net.

DURING the six years that have elapsed since the first edition of this book went to press a great deal of experimental work has been published, and several provocative theories have been proposed by members of the ethological school as well as by representatives of other disciplines interested in the study of animal behaviour. This is, therefore, an appropriate time for the publication of a revised version of the original work. The author has taken his self-assigned responsibility seriously, with the result that the second edition represents a considerable enlargement and re-casting of the initial presentation. The bibliography includes three hundred new references.

Part 2, entitled "Learning", has been increased by sixteen printed pages, and Part 3, "The Learning Abilities of the Main Animal Groups", has been lengthened by thirty pages. The section dealing with cephalopods has been extensively re-written to incorporate recent work dealing with relationships between the nervous system and behaviour in these organisms. Similarly, the section dealing with bird orientation has been completely revised and brought up to date.

Dr. Thorpe's general philosophical orientation, as reflected in the chapter entitled "Directiveness and Purposefulness", remains unchanged. The presentation of "The Nature of Drive and its Place in the Theory of Instinct" retains the original point of view, but is considerably enhanced by an illuminating consideration of physiological mechanisms, other than those involved in learning, which may influence behaviour—as, for example, the coding in the gene in terms of deoxyribonucleic acid.

The treatment of conditioning and trial-and-error learning has been expanded to include references to work done in the U.S.S.R. In some cases the references are to secondary sources but in others primary reports are cited. The treatment of latent learning now includes a discussion of new work dealing with concepts of expectancy and exploratory behaviour.

The chapter on mechanisms of learning contains a great deal of new material, including a review of theories involving the role of ribonucleic acid in connexion with the memory trace. This chapter is also improved by additions to the introductory section in which various neurophysiological theories of learning are discussed.

All in all, Dr. Thorpe's book remains a unique reference source for readers who wish to familiarize themselves with both the historical and modern ethological approaches to an understanding of animal behaviour. It is of additional value because of the careful and detailed attention directed to the experiments and theories which have been published by non-ethological workers.

At the present time there is no competitive volume to *Learning and Instinct in Animals*. It is safe to predict that no successful competitor will be forthcoming for a considerable span of time. This is an excellent book which deserves a place in the library of every serious student of the science of animal behaviour. F. A. BEACH

WILD LIFE AND THE CAMERA

People of the Forest

By Hans Lidman. Pp. 191 (plates). (Edinburgh: Oliver and Boyd, Ltd., 1963.) 42*s*.

THE camera has long proved its worth in the portrayal of wild life, in particular of bird life; indeed, bird photographers in Britain to-day are a large and for the most part a skilled body. But the book now before us is not concerned with British birds. It is by a Swedish naturalist, Mr. Hans Lidman, and is concerned with the wild life of a Scandinavian forest. Mr. Lidman has used his camera with uncommon skill to show us the birds and beasts of this beautiful but stern environment. His pictures are most impressive whether they are of mammals, birds, reptiles, insects, or the world in which they live. There is a landscape, wind-blown snow and tall pines, that suggests storm and winter cold more intensely than any picture I have seen; and there is a view of a few rushes and some sticks rising from the still misty waters of a forest-girt lake which conveys an impression of early morning stillness and peace hard to surpass.

But, of course, it is the studies of birds and beasts that are the great feature of this book. We may justly term it a picture book, though the text is by no means unimportant, consisting of charmingly written descriptions of the forest life and forest creatures under changing conditions, in mid-winter, spring, summer and autumn. It must be remembered that the letterpress is a translation from the Swedish and it is ever difficult to convey the spirit of the original in an alien tongue. So far as one can judge, the translation is successful, bringing before the reader vivid impressions of the vast forests, impressions made the more real, not to say intense, by the photographs.

Where practically all the illustrations are good it is invidious to pick out particular pictures for remark, but the stoat, transformed by its seasonal change of coat into a pure white ermine (p. 10), seems to me an outstanding snapshot. The two common cranes dancing in courtship-display, facing each other with spread wings and in elegant pose, will rouse the envy of all camera-minded ornithologists, and the portrait of a crane at its nest is a superb study.

But in dealing with the subjects of these magnificent pictures, in the matter describing them and their environment, it is regrettable so little use has been made of scientific names. A fine butterfly of swallowtail type is left unidentified, and a stoat, presumably *Mustela erminea*, is called a weasel, though this term is usually reserved for the tiny *Mustela nivalis*. It is true that in Ireland, where the weasel does not occur, the stoat is given this name; all the same, a stoat is generally a stoat and a weasel a weasel to most of us.

Where there is so much to admire we must not carp at such details, possibly due to translation difficulties, but turn back to the illustrations, such as that of a black-throated diver on her nest, lifting her sleek, almost reptile-like head aloft and looking disdainfully around. This volume would make a fine present for a boy or girl with leanings towards Nature. FRANCES PITT

EARTHWORM PHYSIOLOGY

The Physiology of Earthworms

By M. S. Laverack. (International Series of Monographs on Pure and Applied Biology: Zoology, Vol. 15.) Pp. ix+206. (Oxford, London, New York and Paris: Pergamon Press, 1963.) 45*s*.

AS the author emphasizes in his preface, there has been no general account of earthworm physiology since Stephenson's monograph on the Oligochaeta was published more than thirty years ago. Dr. Laverack's book fulfils a need felt by both physiologists and zoologists for an account of the work done since then, much of which is in obscure journals. Earthworms are almost ubiquitous and easily procured, so that it is perhaps not surprising that we know far more of their physiology and structure than we do of other oligochaetes. The subject of the book is, therefore, wisely limited to a review of work done on earthworms, and yet there are occasional digressions, for example, some information is given on respiration of the fresh-water *Tubifex*. There are chapters on digestion and metabolism, on the calciferous glands, the axial field, nitrogenous excretion, water relations, respiration, the physiology of regeneration, neurosecretion, the nervous system, and, lastly, behaviour. There are simple diagrams summarizing the course of digestion, excretion, water-relations and calcium-transport, which are useful in directing attention to what is established and what remains to be demonstrated. The first chapter is a biochemical potpourri; a frankly heterogeneous collation of such interesting topics as the composition of the cuticle, muscle structure, and pigments. In this last section, attention is directed to the presence of protoporphyrin in the skin, a subject mentioned again later (p. 134) in connexion with darkening in light; but the reader is left wondering what other pigments are present, and the reference to Kalmus and others' work (p. 11) without further explanation is annoying.

Such lapses are few. The author has no aversion for colloquialisms and these may be irksome to some readers. The constant use of Latin abbreviations strewn through some paragraphs I find irritating, though some chapters are almost free of them. The description of the chloragocytes and the present view of their function is most useful, but the contact that such cells have with blood vessels is an important point not emphasized. The sense in which the terms 'lipid' and 'fat' (p. 57) are used is not clear, and it may be pointed out that neither the periodic acid–Schiff nor the performic acid–Schiff is a specific test for phospholipids as the student might infer. Later in the book the two types of light-receptor are mentioned and figured (Figs. 57, 58), but there is no mention of the alleged difference in their spectral sensitivity or of the response of one to light increase, the other to decrease, reported by Unteutsch (*Zool. Jb., Abt. 3*, 58, 69; 1937). There are a few typographical errors of which only *Harmathoë* for *Harmothoë* may be mentioned as it may not be obvious to readers; while in Tables 5 and 6 the rate is presumably in hours, and oxygen-uptake is meant, and in Fig. 29 the oxygen-concentration is presumably in ml./l. The only other criticism is perhaps a personal one—the use of oxygen-*tension*—so prevalent among physiologists to-day.

These are all minor points and do not detract from the great usefulness of this book, which undoubtedly forms an essential addition to libraries of departments of zoology and comparative physiology. Dr. Laverack is to be congratulated on presenting such a concise review. It is well bound, clearly printed and is a worthy addition to this series from Pergamon. R. PHILLIPS DALES

FLOWERS OF THE GARDEN

Garden Flowers

By R. D. Meikle (The Kew Series). Pp. 479+15 plates. (London: Eyre and Spottiswoode, 1963.) 30*s*.

IT is largely the effect of the black-and-white illustrations in this latest volume of the Kew Series that sends one's mind racing back to the early herbals, but the feeling soon begins to dawn that the text is very much in keeping. The illustrations are mostly insets into the text and within their rectangular areas plants defy many of the ordinary laws of growth: the slanting Christmas rose (p. 64) and cyclamen (p. 291), the enwreathed flame flower (p. 134), the almost horizontal tubers of Roscoea (p. 390) are merely examples. Then the text, with its

paragraph of description and another of general notes, could well have been modelled on Clusius.

The advertisement on the jacket says "the authors have not shirked the difficulties of technical terms and problems: they have set out to elucidate them while providing enough scientific information to give the student that essential grounding in the classification and nomenclature of plants that is necessary to him before he can proceed usefully to advanced botanical studies". It is true that there are a couple of introductory pages explaining the barest elements of classification and nomenclature: it is true that technical terms are used and are explained in the glossary (perhaps one or two illustrations of dissected flowers would have been helpful): but it is difficult to detect anything that will lead the student on to advanced botanical investigations, or which is necessary groundwork for them. No attempt has been made to include biological information on seedlings, floral functions, seed production or perennation which might entice an interested reader into the paths of botany.

Perhaps it is well to forget any idea that this is a book for potential students. Its public surely lies among those gardeners who take an intelligent interest in wild species. With Harrison's companion volume *Garden Shrubs and Trees*, it gives a very reasonable coverage of garden plants (excluding bulbs) in a more attractive way (and more cheaply) than the standard works of reference like the Royal Horticultural Society's *Dictionary of Gardening*. Its more restricted scope permits a valuable and relatively simple, yet effective, key to the genera. Another feature which enables this book to be recommended is the generally high standard of accuracy in plant names and descriptions. However, two items require comment. Under *Incarvillea* an unnecessary manuscript name has unfortunately been taken up (*I. macrantha* Grierson); the plant in question is to be called *I. mairei* (Lévl.) Grierson. In the glossary 'zygomorphic' is given a correct explanation but two inaccurate synonyms: such a flower is neither 'irregular' nor 'asymmetrical', it is bilaterally symmetrical. B. L. Burtt

DEVELOPMENTS IN PLANT ANALYSIS

Modern Methods of Plant Analysis

Vol. V. Founded by K. Paech and M. V. Tracey, continued by H. F. Linskens and M. V. Tracey). Pp. xxvi+535. (Berlin—Göttingen—Heidelberg: Springer-Verlag, 1962.) DM. 98.

THIS fine work is a continuation of the series *Modern Methods of Plant Analysis*, which is already well known to most workers on plant biochemistry and metabolism. The untimely death of Prof. K. Paech robbed the series of its initiator and co-editor, but the new editorial combination of H. F. Linskens and M. V. Tracey has maintained in this fifth volume the high standards set by the earlier parts. It is now more than seven years since the previous volumes appeared, and in the meantime there have been many developments in techniques for dealing with plant materials. The present volume is intended to supplement and bring up to date the original Volume 1, which was concerned with analytical methods of general application. This aim has been admirably accomplished and the new volume fully justifies the description "Modern Methods".

So far as a single reviewer is able to judge, all the articles are of very high quality. Although they are principally concerned with practical details and applications of the techniques, sufficient theoretical background is included to permit intelligent use of the methods described. The newer techniques, now widely used by workers on plant biochemistry and metabolism, are treated in full. Thus D. J. David deals with "Emission and Atomic Absorption Spectrochemical Methods", K. Biemann with "Mass Spectrometric Methods", H. Moor with "Gefriertrocknung", and B. Breyer with "Polarography and Tensammetry". Chromatography and allied techniques are covered by articles on "Ion-exchange Chromatography" and "Molecular Sieving other than Dialysis" by N. K. Boardman, "Dünnschicht-Chromatographie" by E. Stahl, "Paper Chromatography on a Preparative Scale" by F. A. Hommes and H. F. Linskens, and "Vapour Phase Chromatography" by S. P. Burg. Other articles mainly concerned with macromolecules include "Determination of Size, Shape and Homogeneity of Macromolecules in Solution" by I. J. O'Donnell and E. F. Woods, "Optical Rotatory Dispersion. Its application to Protein Conformation" by E. F. Woods and I. J. O'Donnell, "Diffuse Röntgenkleinwinkelstreuung" by O. Kratky, and "Immunological Methods" by J. A. van der Veken, D. H. M. van Slogteren and J. P. H. van der Want. There are also more specialized articles by H. Prat on "Méthodes Calorimétriques pour l'Analyse les Végétaux", by A. E. Dimond on "Surface Factors affecting the Penetration of Compounds into Plants" and by J. V. Possingham and P. S. Davis on "Fallout Contamination in Plants".

Two articles in particular have a considerably wider field than that of plant analysis and will be of great interest to many plant physiologists. The contribution of W. L. Butler and K. H. Norris on "Plant Spectra: Absorption and Action" deals with light-scatter phenomena, absorption spectra, action spectra and fluorescence excitation spectra. This article includes an account of the discovery and properties of phytochrome; also the role of spectra in the investigation of photosynthesis. The concise but comprehensive account by A. C. Hildebrandt on "Tissue and Single Cell Cultures of Higher Plants as a Basic Experimental Method" reveals that this technique is a useful experimental method and no longer merely a botanical curiosity.

No laboratory concerned with plant biochemistry or physiology should be without this valuable book. Although it is a German publication, many workers on both sides of the Atlantic will benefit from the fact that of the eighteen articles fourteen are written in English. As a final comment, it should be said that the volume is beautifully printed and produced. A. Allsopp

DEVELOPMENT OF HEATH SOILS

The Development of British Heathlands and Their Soils

By G. W. Dimbleby. (Oxford Forestry Memoirs, No. 23.) Pp. 120+8 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1962.) 60*s*. net.

MANY thousands of acres in Britain have been planted with conifers by the Forestry Commission; most of these plantations are on heath soils where fertility is known to be low, yet the very existence of these trees depends on the maintenance of a minimal level of nutrients.

This *Memoir* investigates the development of heath soils at selected sites, chiefly in Yorkshire and in the vicinity of the New Forest, using as data soils which have been buried for varying periods by ancient earthworks. Archæological and other evidence is used to date these soils, and comparisons are made with soils of similar date from other parts of Europe. The main body of the work is followed by a substantial appendix in which detailed information on pollen spectra and soil characteristics from the 32 sites investigated form the experimental evidence for the conclusions.

In a brief discussion on methods, reference is made to a previous work by this author for the details of pollen analysis of relatively recent deposits. This is a highly controversial subject and it would not, I feel, have been out of place to have included some reference to the inherent weaknesses involved, such as the movement of pollen from one horizon to another and the variable resistance of pollen to bacterial and other action. A section on the development of soil profile indicates the various types of podzol which have been found at the different sites; the

author concludes that a certain amount of podzolization did, in fact, take place under forest, but much of the degradation is secondary. Of the possible degrading agents involved, climate is clearly important, as is vegetation cover, but rather conflicting evidence suggests that neither of these is of overriding importance, and the greatest influence seems to have been the nature of the parent material. A very interesting section is that in which the transition from forest to heath is related to various agencies and especially to the part played by Neolithic Man, though it is stressed that the use of fire by Mesolithic and possibly also by Palæolithic Man may have had a greater effect than is often realized. Some comments on the regeneration of degraded soils show that this relatively uncommon phenomenon is usually associated with a grass cover and, therefore, with agriculture, but the depth to which such regeneration occurs suggests that trees may also play an important part. Rather curiously, there is no mention of the extensive work by Ovington on the circulation of nutrients in conifer plantations, especially on the heaths of the Breck.

The author is clearly concerned that the policy of planting conifers on already degraded heath soils can result only in further degradation, though he stops short of stating what positive steps could be taken to overcome this. It is implicit in his general conclusions that some soils could become so exhausted that they would cease to support a continuous vegetation cover at all.

It seems a pity that a *Memoir* of this type could not be bound in a hard cover; but there can be no excuse for neither the title nor the author's name appearing on the spine. While the printing of the text is fully up to the standard expected of the Oxford University Press, the same cannot be said for the coloured plates. I sympathize with the author's contention that soil profiles are best illustrated by colour photographs, but the reproductions provided give only the most general impression of the various horizons.

R. B. Ivimey-Cook

VEGETATION AND HYDROLOGY

Vegetation and Hydrology

By Dr. H. L. Penman. (Technical Communication No. 53 of the Commonwealth Bureau of Soils, Harpenden). Pp. v+124. (Farnham Royal: Commonwealth Agricultural Bureaux, 1963.) 20*s*.

THE scientific problems underlying water conservation have been bedevilled by the diversity of interests and opinions pertaining to the hydrology of a land surface. The available evidence is often derived from technical investigations by agriculturists, foresters or water-engineers, working from basically different assumptions, while the approximate nature of the field techniques used has contributed greatly to the confusion. Hence this publication may be welcome, not only because it gives a survey of the pertinent literature, but also because it attempts to establish modes of approach to the underlying problems and to define them in general and scientific terms.

If climate, and especially rainfall, is determined by the movement of air masses, the only site factor that may control evaporation in the water-cycle is the vegetation cover. Assessments of the relative importance of this factor illustrate extremely well the insecurity of the premises on which alternative views depend and, in particular, the extreme differences in outlook which result from under-estimates of the importance of turbulence and of 'edge' effects in evaporation; the contrast, in short, between estimates based on small sample plots or potted plants, and those derived from a complete and extensive vegetation cover. The survey of the evidence suggests that decisive experiments in this field have not yet been achieved, so that the working hypothesis used in the final chapter may still be the safest approach. It is in essence Rakhmanov's conclusion for catchment area investigations that forest cover does not accelerate evaporation, which depends, therefore, mainly on weather. Dr. Penman leaves the data to speak for themselves. He has, however, indicated the arguments which must be applied to the meteorological approach, has dealt with the difficulties of accurate rain-gauging, the effects of vegetation in intercepting rain, and in increasing the infiltration of water while lessening run-off and soil erosion. He has given also a good discussion of the main problems involved in estimating potential evaporation. This is, therefore, much more than a technical summary, and is a work which will appeal to those with wider interests.

W. H. Pearsall

COMMONWEALTH UNIVERSITIES YEARBOOK

Commonwealth Universities Yearbook 1963

A Directory to the Universities of the British Commonwealth and the Handbook of their Association. Edited by J. F. Foster and T. Craig. Pp. xxxii+1826. (London: Association of Universities of the British Commonwealth, 1963.) 105*s*.; 15 dollars.

"EDUCATION may be said to be permanently in a state of transition and this is to the good. Without change there is no development; without change there is only decay." Thus wrote the reviewer of the second edition (1915) of what was then called *The Yearbook of the Universities of the Empire*, a directory compiled and published by the University Bureau of the British Empire (*Nature*, 96, 317; 1915). In the years that have followed there have been such great developments that the *Yearbook*, which was then 717 pages, dealt with 54 universities and affiliated colleges, and cost 7*s*. 6*d*., now, in its fortieth edition, extends to 1,826 pages, deals with 150 universities and affiliated colleges and costs 105*s*. Moreover the Bureau, founded in 1913, has very recently become the Association of Commonwealth Universities and the directory *The Commonwealth Universities Yearbook*. The fortieth edition thus appears in the Jubilee year of the founding body.

The *Yearbook* is published as a directory to university institutions in all countries of the Commonwealth and is not restricted to membership of the Association. Essentially it is divided up into 18 sections dealing with the countries of the Commonwealth. Each of the sections has a "national introduction", primarily intended as a functional guide for people who wish to attain a general background on university education in that particular country. Then follow the separate university entries and, department by department, their academic staff. At the end of each university section are given details of administrative and other staff, affiliated colleges and halls of residence and general information. In so doing the *Yearbook* fulfils the function of providing basic data to assist a student proposing to go to a Commonwealth country. In addition to the particulars, for example, of "first degrees" and "higher degrees", there is a detailed chart of "Subjects of Study".

In all there are seven appendixes. Appendixes 1 and 2 contain full details of the universities of the Republic of Ireland and the Republic of South Africa. Appendix 3 is a summary of the admission requirements of universities in Australia, Canada and the United Kingdom. Appendix 4 deals with information pertaining to students from other countries in United Kingdom universities. Appendix 5 deals with British academic institutions outside the Commonwealth, and Appendix 6 gives a short bibliography. Details of the Commonwealth scholarship and fellowship plan are dealt with in Appendix 7, and finally, Appendix 8 gives a full account of the Association of Universities of the British Commonwealth. There are excellent general and name indexes.

Man and Beast

By Major C. W. Hume. Pp. 222. (London : Universities Federation for Animal Welfare, 1962.) 15*s*.

THIS is a compilation, by Margaret Pattison, from the writings of Major Hume on matters of animal welfare, and is part of the campaign waged by the Universities Federation for Animal Welfare to ensure that the subject is brought to the attention of all concerned with the prevention of cruelty in general and with the use of animals for the purposes of man. It is well to provide in one small book the essentials of the arguments so well brought out over many years and many of the themes deserve the emphasis of repetition.

There is no doubt about the value of such a body as the Universities Federation. Even the most dedicated research worker can reasonably be reminded that he must constantly give consideration to the ethical and humanitarian aspects concerning animal experimentation. Human nature is such that constant reminders about responsibilities must be accepted. In the exploitation of domestic animals for human food, materials and for work the well-being of the animal is important. Habituation to the more unpleasant features of the necessary practices involved in the exploitation of animals can blunt the susceptibilities of the individual, and actual cruelty can be condoned.

In the past half-century or so much has been done in many countries to prevent suffering that can arise from certain practices. The compulsory use of anæsthesia for certain routine operations has done much in this direction. It is, however, well to emphasize that some legislation in this direction covered practices which a past generation of veterinary surgeons had accepted because animals had from time immemorial been given little consideration on matters related to pain; when enlightened members advocated the necessarily more elaborate procedures now used there had been some lack of support. When a strong trade union has an influence on a regular, seasonal, peripatetic procedure, such as sheep shearing, where profit is closely bound with rapid turnover of the operation and time an all-important factor in profit, insistence on rigid routine and on the necessary local facilities and labour ready for the visiting 'team', the animal concerned might receive less consideration than desirable. With the developments of 'factory' methods for the rearing of birds and animals for the table, where thousands and not tens may be the units, there was never greater need to emphasize that the individual animals have their rights.

This book will be an important reminder that humanity, as well as profit, is as desirable as ever. W. A. Pool

Rutherford at Manchester

Edited by J. B. Birks. Pp. x + 364 + 7 plates. (London: Heywood and Co., Ltd., 1962.) 60*s*.

THE fiftieth anniversary of the discovery of the nucleus by Rutherford and his collaborators in Manchester was celebrated in 1961 by an international conference. This volume records the historical portions of this conference in addition to much other material relating to Rutherford's Manchester period. About half the book is taken up with reprints of the papers by Rutherford, Bohr, Moseley and others which first reported these discoveries. Almost all the remainder consists of reminiscences by Rutherford's students and collaborators. The result is rather heterogeneous. but in the manner of a cinematic montage is quite effective in creating a human picture of the great physicist.

The 'cult of personality' in physics has always been prominent, and is not necessarily a bad thing. Indeed some physicists would say that progress in physics is from personality to personality. The tendency is bad, however, when the influence of one powerful personality holds back the emergence and recognition of the next. That Rutherford himself would have deplored any such effect is clear from a reading of this book. Though he enjoyed being a world figure and could be ruthless in getting results, yet it is clear that he also enjoyed nurturing and developing young physicists with fresh ideas and was completely fair in giving them full credit. Great physicists have not always shown such tolerance as they grew older and it is clear that Rutherford was a great man as well as a great physicist.

It is also clear that although Rutherford used rather simple and cheap apparatus for much of his work, he was delighted with every new technical development which opened up new experimental fields. He had no interest in technical developments as ends in themselves, but he still seized on the best equipment available for studying his interest of the moment.

This book is valuable not only for the factual history which it preserves but also for the inspiration and encouragement it may give to to-morrow's 'personalities' of physics. E. B. Paul

Atomic Theory and the Description of Nature

Four Essays, with an Introductory Survey. By Prof. Niels Bohr. First printed 1934. Pp. vii + 119. (Cambridge: At the University Press, 1961.) 8*s*. 6*d*. net; 1.65 dollars.

OF the four essays by the late Prof. N. Bohr two were originally published in *Nature* in 1925 and 1927, the third in the *Naturwissenschaften* and *Fysisk Tidsskrift* in 1929. First issued in one volume in 1934, they were reprinted in 1961 and a preface was added by Prof. Bohr. Most physicists will be grateful that this little volume is available again. The interest of the four articles is mainly due to the insight one can obtain of the fundamental changes of outlook introduced by the new quantum mechanics. By 1929 Dirac, Heisenberg, Schrodinger, Born and others had provided the mathematical formalism which made it possible to obtain the truly sensational results which the new theories provided. However, the necessity for "a radical departure from ordinary pictorial description and accustomed demands of physical explanations" was not accepted by all physicists (for example, Einstein).

The articles are free from mathematical formulæ, but nevertheless demand close attention to appreciate the wide sweep and the depth of the arguments; they ought to be made compulsory for the young theoretical physicists who are so often virtuosi in the manipulation of algebra (and proud of it) but occasionally shaky in deeper questions of what they are really doing. E. Bretscher

World List of Forensic Science Laboratories

Edited by Dr. D. Patterson. Pp. iii + 30. (London: Forensic Science Society, 107 Fenchurch Street, 1963.) 7*s*. 6*d*.; 1.50 dollars.

THIS excellent publication meets a long-felt need both by forensic scientists and by those who desire their services. It comprises 280 entries from 42 countries and lists such details as the title of each laboratory, its address and telephone number, and the name of its director. No attempt is made to define 'forensic science', but it is evident that the interpretation is wide. While it is not in any sense an 'approved' list, much of the information has been derived from official sources.

The very existence of a forensic 'Who's Who' is certain to foster greater co-operation internationally. Perhaps the first manifestation of this will be by way of the response to the Editor's invitation to assist in the preparation of an even more comprehensive list in due course. In this connexion, laboratories in Germany are conspicuous by their absence, and the Communist countries have but one representative—the Scientific Research Institute of Forensic Medicine, Moscow.

R. A. Outteridge

MECHANISM OF POLYRIBOSOME ACTION DURING PROTEIN SYNTHESIS

By HOWARD M. GOODMAN and Prof. ALEXANDER RICH
Department of Biology, Massachusetts Institute of Technology, Cambridge, Mass.

POLYRIBOSOMES or polysomes are clusters of ribosomes which are held together by RNA. They can be seen in the electron microscope as linear arrays of ribosomes which are linked by thin strands, 10–15 Å in diameter[1,2]. Very low concentrations of ribonuclease convert these ribosomal clusters into single ribosomal units[3]. It has been shown that the polysome is the site of protein synthesis in investigations with reticulocytes[3,10], liver[4], HeLa cells[5], and slime moulds[6].

When polyribosomes in reticulocytes were initially discovered, it was assumed that the RNA holding the ribosomes together was the messenger RNA which contains the nucleotide sequence information necessary for the synthesis of the completed polypeptide chain[3]. This assumption was a natural outgrowth of previous experiments which showed that the synthetic messenger, polyuridylic acid, could form aggregates with bacterial ribosomes[7,8,8a]. Recent experiments in both normal and polio-infected HeLa cells have confirmed this initial assumption[5]. Reticulocytes manufacture primarily a single protein molecule, hæmoglobin. It has been shown that these polysomes are predominantly clusters of five ribosomes, although there is also a normal component of tetramers and hexamers in the cells[1]. This natural distribution was interpreted in terms of a mechanism whereby ribosomes become attached to one end of the linear polyribosomal cluster and then gradually move along the messenger strand while the polypeptide chain increases in length. At the end of the messenger chain the ribosomes are believed to detach and the polypeptide chain is released. Models of this type have also been considered by Gilbert[9], Gierer[10], and Noll *et al.*[11]. This mechanism provides a ready explanation for the naturally occurring distribution of polysomes in reticulocytes, that is, predominantly pentamers, with associated tetramers and hexamers, since random attachment at one end and detachment at the other end of the messenger strand would produce this distribution. Other evidence supporting an interpretation of this type was the observation made in electron micrographs that the ribosomes in the polyribosomal clusters are separated by gaps of 50–150 Å (refs. 1 and 2). This makes it unlikely that the polypeptide chains could be made by growing first on one ribosome and then somehow jumping from one to another to complete the chain.

A schematic model of this concept of polysome function is shown in Fig. 1. An oncoming ribosome without a polypeptide chain (diagonal shading) is shown attaching at one end of the polysome, while at the other end a ribosome with its completed polypeptide chain is released and the chain is freed. The diagram shows five ribosomes, which would be found in the case of a messenger RNA long enough to code for a 150 amino-acid polypeptide chain the size of hæmoglobin. However, similar models could be drawn involving longer messenger chains with more ribosomes which would be active in the synthesis of longer polypeptide chains.

In this article we describe three types of experiments which were designed to test this model of polyribosome function. In these experiments we used HeLa cells which contain a broad distribution of polyribosome size[5]. Electron micrograph investigations have shown that the larger clusters contain approximately forty ribosomes[12]. One of these experiments is a test of ribosomal attachment. Another demonstrates the release of polypeptide chains. The last shows that all polyribosomes are active in protein synthesis and discharge their ribosomes during *in vitro* incubation.

Ribosomal attachment experiments. HeLa cells were grown in suspension culture, and cytoplasmic extracts prepared by a slight modification of the method described by Penman *et al.*[5]. The cells were chilled, centrifuged, washed and re-suspended at 10^8 cells/ml. in a standard buffer (0·01 M *tris* buffer, *p*H 7·8, 5×10^{-3} magnesium acetate, 5×10^{-3} M potassium chloride and 6×10^{-3} M mercaptoethanol). The cells were then broken open with a Dounce homogenizer, and the nuclei and mitochondria removed by centrifugation (10 min at 4,500*g*).

For the ribosomal attachment experiments HeLa cells were grown for approximately one generation in medium supplemented with tritiated uridine. Tritiated single 74 *S* ribosomes were isolated as described in Fig. 2. During this isolation procedure, the single ribosomes were separated from polysomes by centrifuging them twice on sucrose gradients. Only the centre fractions from the 74 *S* peak were used.

In this experiment the tritiated ribosomes were added to an unlabelled cytoplasmic extract and incubated for 3 min under various conditions as shown in Fig. 2. Following this incubation, the materials were chilled, placed on a sucrose gradient, centrifuged and analysed for optical density and radioactivity. In Fig. 2 the direction of sedimentation is to the left. There is a sharp peak in both

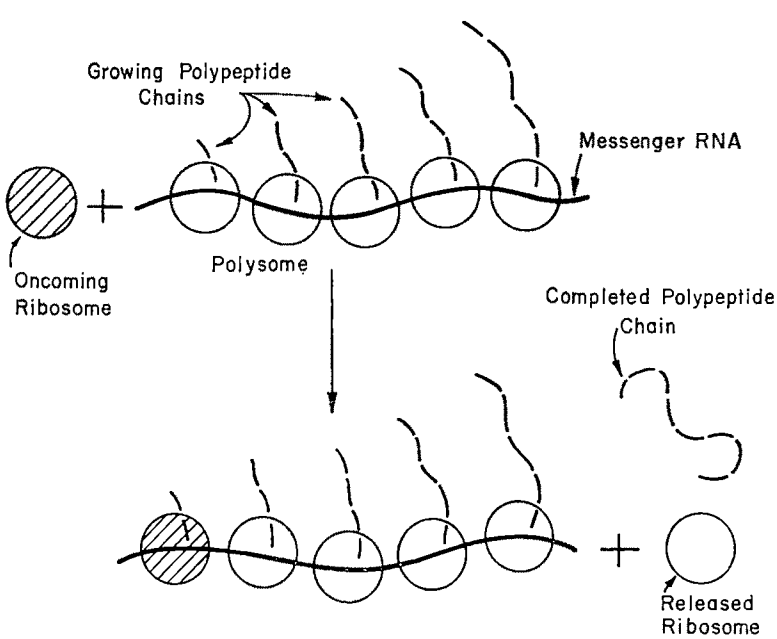

Fig. 1. A schematic model of polysome function

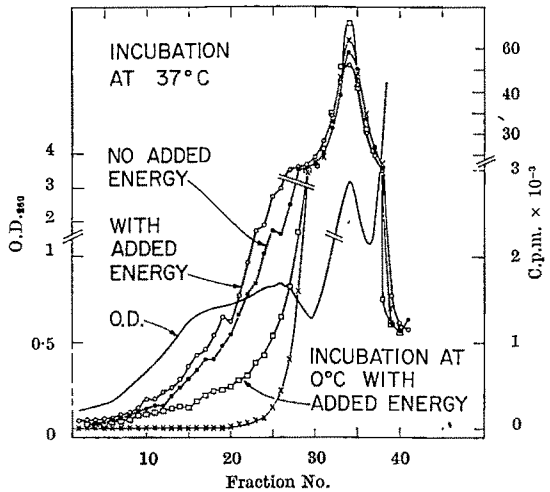

Fig. 2. Attachment of tritiated 74 *S* ribosomes to polysomes. 0·2 mg of 74 *S* tritiated ribosomes were added to 1·2 ml. of cytoplasmic extract and then incubated for 3 min. After incubation, the samples were chilled, and layered on a linear 15–30 per cent w/w sucrose gradient (containing 0·1 M *tris*, *p*H 7·8, 0·05 M potassium chloride and 0·005 M magnesium acetate). The material was centrifuged for 105 min at 25,000 r.p.m. in a Spinco *SW* 25 rotor. The bottom of the tube was punctured and the contents of the gradient were continuously analysed for optical density at 260 mμ in a Gilford spectrometer. Fractions were collected and counted in a scintillation counter. The curves are as follows: ribosomes alone (×), incubation at 37° C with no added energy (●), and incubation at 37° C with added energy (○), incubation at 0° C with added energy (□). Forty-one fractions were collected. The peak tube 34 is the 74 *S* ribosomes. The components added for energy were 2·5 μM/ml. ATP, 0·3 μM/ml. GTP, 12·5 μM/ml. phosphoenolpyruvic acid and 50 γ/ml. crystalline pyruvate kinase. The tritiated ribosomes were isolated by preparing cytoplasmic extract from cells grown with tritiated uridine (2·6 c./mM; 1 mc./ml. of culture medium) and then preincubating for 30 min to release single ribosomes from polysomes. The preincubation system contained 10 μM/ml. *tris* buffer (*p*H 7·8), 5 μM/ml. magnesium acetate, 5 μM/ml. potassium chloride, 6 μM/ml. mercaptoethanol, the energy system listed above and 0·07 μM/ml. each of 20 naturally occurring amino-acids. Following preincubation, the ribosomes were centrifuged (2 h, 105,000*g*), the pellet resuspended in unlabelled supernatant and then centrifuged for 325 min on a sucrose gradient. The 74 *S* peak was collected and dialysed overnight against standard buffer. The ribosomes were again centrifuged into a pellet and the 74 *S* fraction was again isolated on a sucrose gradient

optical density and radioactivity near tube 34, which is associated with single 74 *S* ribosomes[13]. The material to the left of this peak represents the polysomes. The optical density shows a maximum that sediments about 2·5 times as fast as the 74 *S* ribosomes. This maximum is a five ribosomal peak, and further down the gradient there is a long tail of optical density which represents polysomes of increasing length. This distribution is characteristic of a mammalian cell which is manufacturing a large number of different proteins[5]. The tritiated ribosomes alone sediment as a 74 *S* peak with a diffusion base, as indicated in Fig. 2. However, if the tritiated ribosomes are added to the cytoplasmic extract, it can be seen that some of the tritiated ribosomes now sediment with the polysomes. Incubation at 0° C results in some displacement of these ribosomes. However, incubation at 37° C in the cytoplasmic extract results in a considerable increase in the number of tritiated ribosomes which are attached to the polysomes, and the addition of more energy results in a further increase. These experiments show that the ribosomes have become attached during this short period of incubation so that they now can migrate through the sucrose gradient with the more rapidly sedimenting polysomes. In repetitions of this experiment, the addition of energy to the cytoplasmic extract resulted in up to a 100 per cent increase in the number of tritiated ribosomes attached as compared with the number attached in the absence of added energy.

Experiments of the type shown in Fig. 2 can be interpreted quantitatively. In particular, we can ask what is the relation between the number of attached labelled ribosomes and the number of polysomal or messenger RNA ends as a function of polysomal size. We can calculate the number of polyribosomal ends at any point in the gradient. As shown in the schematic diagram in Fig. 1, the number of available ends must be inversely proportional to the number of ribosomes found in the polysomal chain. We have been able to determine the number of ends in the following manner.

The optical density at any particular point in the sucrose gradient is a measure of the number of the ribosomes which are found in each fraction[13]. The position of a particular fraction in the sucrose gradient is related to the number of ribosomes in the polyribosome chain. This number has been determined in several ways. In some gradients it is possible to see fine structure or contours in the optical density profile which go out to as many as 10 or 12 ribosomal units. This method of counting is an extrapolation of the type of result which was described in the hæmoglobin polysomal cluster where the peaks of optical density were found associated with a fixed number of ribosomes as determined by electron microscopic examination[3]. In addition, it is possible to calculate an approximate sedimentation constant for polyribosomal clusters by assuming that they exist in the form of an ellipsoid of revolution[10]. Finally, the number of ribosomes have also been determined in HeLa gradients directly by electron microscope studies[12].

Thus knowing the number of ribosomes in a fraction and the length of the polyribosome chain, it is possible to plot a curve, as shown in Fig. 3, of the number of polyribosome ends as a function of the number of ribosomes in the polysome chain. This curve is shown in Fig. 3, together with a curve showing the number of ribosomes found in the various fractions. By using the known specific activity of tritiated ribosomes, we can interpret an experiment such as that shown in Fig. 2 in terms of the number of labelled ribosomes which are attached to the various polyribosomal clusters. These experimental points are shown by the solid circles in Fig. 3, and, with a suitable adjustment of ordinate, it can be seen that these points fall almost precisely on the calculated solid

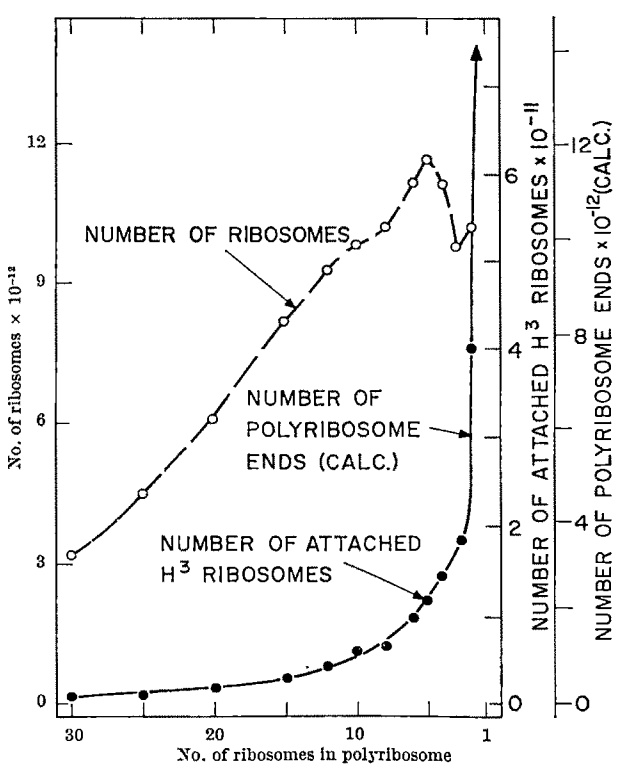

Fig. 3. The relation between the number of polyribosome or messenger RNA ends and the number of attached tritiated 74 *S* ribosomes after 2 min of incubation at 37° C in cytoplasmic extract with added energy. The dashed line shows the number of ribosomes in various fractions as a function of the size of the polyribosome. The solid line is the calculated number of ends and the solid circles are the experimental points

curve showing the distribution of polysome ends. In the experiment in Fig. 3, approximately 5 per cent of the polyribosome ends have a labelled ribosome attached to them after 2 min of incubation at 37° C in the presence of added energy. Since the number of labelled single ribosomes was approximately one-third the number of unlabelled single ribosomes in the cytoplasmic extract, it can be estimated that approximately 20 per cent of the polysomes have added a ribosome during this short time period. However, the concentration of both ribosomes and polyribosomes in the cytoplasmic extract is less than one-tenth that which prevails inside the cells *in vivo*. Therefore, it is quite likely that this amount of attachment represents only a small fraction of what is going on *in vivo* during the same time period.

The ribosome attachment experiments in Fig. 2 show that it is possible to obtain some attachment to a polysome at 0° C, even though there is no concomitant synthesis of a polypeptide chain at that temperature. Raising the temperature results in the synthesis of a polypeptide chain, and the attachment of more ribosomes. This suggests that the protein synthetic mechanism may be divided into two parts, one of which may involve the attachment of a ribosome to the end of the messenger RNA chain. This reaction can occur at 0° C even though the enzymatic reactions necessary for protein synthesis are not proceeding. In this regard it should be pointed out that ribosomes from *E. coli* have been shown to attach to polyuridylic acid at 0° C in a similar manner[8].

This experiment shows that the polysomes are able to have single ribosomes attached to them and, furthermore, the number attached is independent of the length of the polyribosome. This may be interpreted as indicating that all polysomes have the same number of attachment sites, since the number of attached ribosomes is proportional to the number of ends. Considering the polarity of the messenger RNA chain, we believe this indicates a single attachment site as shown in Fig. 1.

Protein detachment experiments. In order to demonstrate the detachment of ribosomes and release of completed polypeptide chains, another type of experiment was devised. The polyribosomes were labelled *in vivo* by exposing HeLa cells to a short pulse (1·5 min) of amino-acids labelled with carbon-14. Following this, the cytoplasmic extract was prepared, and the ribosomes and polyribosomes were then centrifuged into a pellet and the supernatant decanted. This pellet, with the attached labelled nascent protein, was re-suspended in an unlabelled supernatant of the original volume. Thus the system was reconstituted with unlabelled amino-acids and *s*RNA, and the only radioactivity present in the system was that which had been pelleted with the ribosomes.

This material was then incubated *in vitro* with energy at 37° C and samples were collected at various time periods, as shown in Fig. 4. At zero time it can be seen that most of the counts are associated with the polyribosomes. The fact that the optical density peak in the polysome region is different from that of unpelleted extract as shown in Fig. 2 indicates that the polysomes have suffered a certain amount of breakdown due to the pelleting and re-suspension[3].

Further evidence for this breakdown is a small peak of radioactivity in the single ribosome region. This peak would not be there unless there had been some breakdown. However, it is clear that the bulk of the counts are associated with the polysome region. As incubation proceeds, it can be seen that the radioactivity in the polysome peak gradually disappears and shifts to the right, that is, it is associated with smaller

Table 1. Distribution of Radioactive Protein during *in vitro* Incubation

Time (min)	Total counts	Counts in various fractions (per cent) Polyribosomes	Single ribosomes	Soluble protein
0	15,146	75	7	18
5′	14,276	58	11	31
10′	15,135	42	12	46
25′	17,158	18	14	68

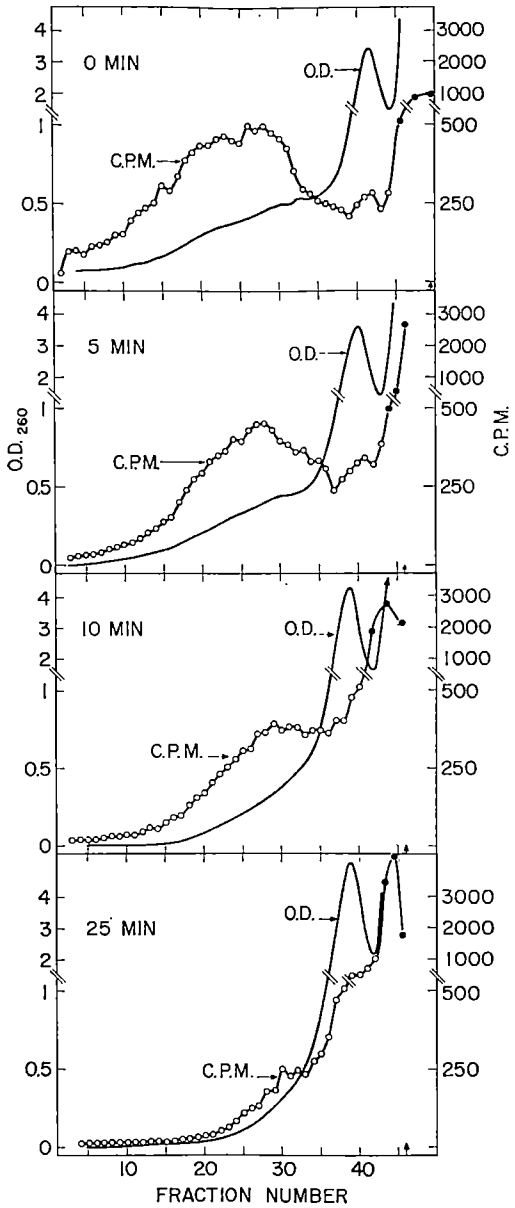

Fig. 4. Sucrose gradients showing the results of an *in vivo* labelling with ^{14}C-amino-acids followed by an unlabelled *in vitro* incubation of the ribosomes. One litre of logarithmically growing HeLa cells (4 × 10^5 cells) were labelled for 1·5 min with 100 μc. of ^{14}C-algal protein hydrolysate (1·6 mc./mg) as described previously (ref. 5). Cytoplasmic extract made from these cells was centrifuged and the pellet was resuspended in 6 ml. of unlabelled supernatant. After the addition of energy, the material was incubated at 37° C and 1·5 ml. samples were removed at 0, 5, 10 and 25 min for sucrose gradient analysis. The fractions were prepared for counting by the addition of 0·5 mg of serum albumin carrier protein and trichloroacetic acid was added to a final concentration of 5 per cent. The precipitate was plated on 'Millipore' filters and counted. The samples in the soluble protein region (●) were prepared for counting by a modification of the method of Siekevitz (ref. 15). The vertical arrow on the base-line indicates the last fraction

polyribosomes. However, accompanying this, is a substantial increase in the amount of labelled soluble protein which is found at the top of the gradient. The distribution of radioactivity during this incubation process is shown in Table 1. At the starting time 75 per cent of the counts are found in the polyribosomes and 18 per cent in the soluble protein (which is probably due to trace amounts of the radioactive supernatant in the pellet). The 7 per cent in the single ribosome peak is due to breakdown associated with sample manipulation. After incubation for 25 min, it can be seen that the polyribosome counts now have only 18 per cent of the total counts, while 68 per cent are found in the soluble protein. Thus

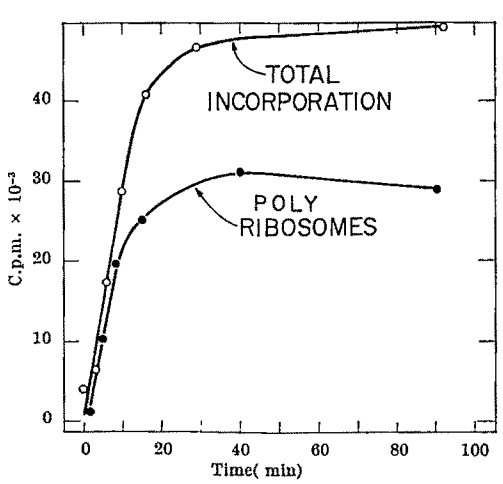
incubation under conditions which favour protein synthesis has resulted in a release of the bulk of the radioactivity associated with the ribosomes and their accumulation in soluble protein.

Earlier experiments with reticulocytes demonstrated that the effect of ribonuclease treatment is to bring about a quantitative transferal of both polysomes and their nascent protein radioactivity to the single ribosomal peak[3]. Thus the increase from 7 to 14 per cent of the counts associated with single ribosomes may be related to residual ribonuclease activity present in this system. However, we have carried out other experiments in an attempt to assay the amount of ribonuclease present in the cytoplasmic extract from HeLa cells. Polyuridylic acid labelled with carbon-14 was added to the incorporating system and its half-life determined during incubation at 37° C. In these experiments it was shown that the half-life is about 50 min. This is in marked contrast to the half-life of less than 1 min during incubation with an *E. coli* cell-free system[8]. Our experiments, therefore, suggest that there is little ribonuclease free in the HeLa system.

The gradual decrease in the size of the polysomes as the incubation proceeds suggests that the amount of attachment of single ribosomes to polysomes is perhaps much less than the amount of detachment. Thus during this incubation a polysome containing, for example, five ribosomes would gradually discharge individual ribosomes and polypeptide chains until finally it is left with the last ribosome attached to the messenger RNA in the process of completing its chain. It is quite likely that some of the radioactivity associated with the single ribosomal peak may be derived from this source.

These experiments demonstrate that *in vitro* incubation with an amino-acid incorporating system results in the liberation of radioactive polypeptide chains which were formed during an *in vivo* labelling. At the same time single ribosomes become detached from the polyribosomes. Results similar to these have been obtained with reticulocyte polysomes[14].

Amino-acid incorporation in vitro. Another kind of experiment has been carred out to show the effect of *in vitro* incubation on polyribosomes. In these experiments unlabelled cytoplasmic extract was made and to it were added amino-acids labelled with carbon-14 and a source of energy. Fig. 5 shows the time course for the incorporation of ^{14}C-amino-acids into protein both on the polyribosomes and in the entire extract. For the first 10 or 15 min incorporation is approximately linear. Following that,



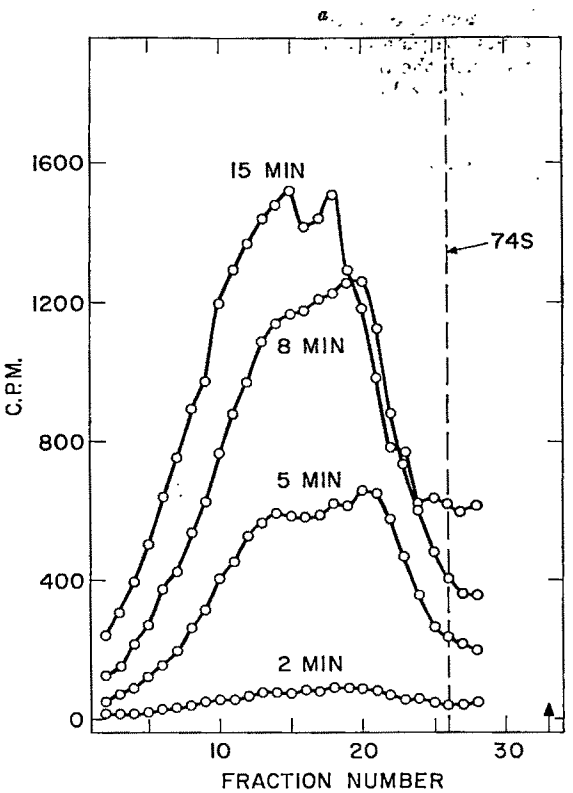


Fig. 5. Kinetics of ^{14}C-amino-acid incorporation into cytoplasmic extract. The incubation conditions were as in Fig. 2, except that 8 μc./ml. of ^{14}C-algal protein hydrolysate was added at zero time. 0·1 ml. samples were removed at various time periods, and the data is presented for the 1·5 ml. samples which were used in Fig. 6. The total incorporation was counted by the modified Siekevitz method (ref. 15). The polyribosome curve was obtained from the sucrose gradients shown in Fig. 6*a*

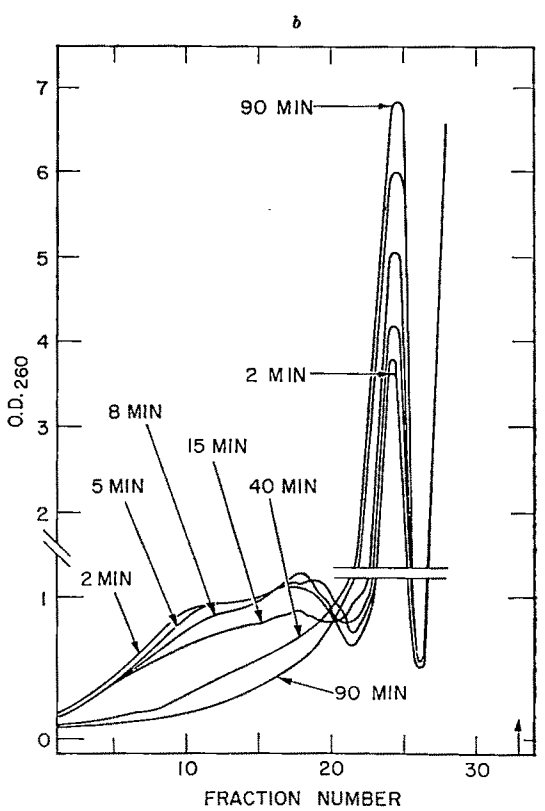

Fig. 6. Sucrose gradient analysis of *in vitro* amino-acid incorporation. The conditions for incorporation are as in Fig. 4. 1·5 ml. samples were removed at various time periods and analysed on the sucrose gradient as described previously. (*a*) The radioactivity associated with the polysome peak for various time periods. (*b*) The optical density of gradients at various time periods of *in vitro* incubation. The peak height in the 74 *S* region rises steadily with time from 2 min to 90 min

there is a decrease in the rate of incorporation of ^{14}C-amino-acids. A plateau is reached in the number of counts associated with the polyribosomes and the total incorporation also plateaux but at a higher level.

Samples were isolated at various intervals during this incubation, chilled and then placed on the sucrose density gradient. The optical density and radioactivity associated with these fractions is shown in Figs. 6*a* and *b*. In Fig. 6*a* it can be seen that the radioactivity is incorporated continuously throughout the entire polysome region. Thus all sizes of polysomes are active in protein synthesis in agreement with the attachment experiments which showed that ribosomes are attached to all the different lengths of the polysomes. In addition, it can be seen that the total radioactivity associated with the polysomes increases with time of incubation. However, a difference can be seen between incorporation into smaller polysomes in contrast to the incorporation into larger polysomes. Between 8 and 15 min the penta- and hexa-ribosomal units (fractions 17–18) incorporate somewhat less than the polysomes of length near 30 (fractions 5–6). This might be expected if the smaller polyribosomes are making smaller polypeptide chains. In the steady state these polyribosomes have less radioactivity than those making longer polypeptide chains. An observation similar to this has been made by Noll *et al.*[11] in their experiments with rat liver polyribosomes.

Fig. 6*b* shows the optical density profile for varying times of incubation. It can be seen that the effect of incubation is to bring about a gradual decrease in the size of polyribosomes as the incubation proceeds. The longer polyribosomes at the left-hand side of the gradient begin to decrease in number and associated with this is a gradual rise in the optical density of the monomer peak. It has been shown that this reaction is energy dependent. This type of result would be anticipated in an *in vitro* system in which the rate of attachment of new ribosomes to a polyribosome is much less than the rate of detachment. Thus the effect of incubation is to bring about a quantitative conversion of polyribosomes into single ribosomes. This effect has also been described with liver polyribosomes[11].

Thus, in summary, the demonstration of ribosomal attachment, polypeptide chain release and the release of ribosomes from polysomes during incubation are consistent with the general scheme of polysomal function during protein synthesis as outlined in Fig. 1.

We thank Drs. J. E. Darnell, S. Penman, J. R. Warner as well as M. J. Madden and P. Samuelson for their assistance. This work was supported by research grants from the U.S. Public Health Service and the U.S. National Science Foundation.

THE GALAXY AND THE MAGELLANIC CLOUDS

THE International Astronomical Union symposium No. 20 on "The Galaxy and the Magellanic Clouds" has recently been held in Australia—the first of the Union's symposia to be held in the southern hemisphere. It was co-sponsored by the International Astronomical Union and the Union Radio-Scientifique Internationale, and conducted under the auspices of the Australian Academy of Science. In some ways the symposium was a successor to the Groningen (1953) and Stockholm (1957) conferences on co-ordination of galactic research. However, the choice of papers placed special emphasis on southern problems in the Galaxy, particularly the nearby spiral arms, and the nature of the galactic centre region. Being the first major conference on the Magellanic Clouds, there was a feast of papers on the structure and evolution of our closest neighbour galaxies.

Thirty overseas astronomers, many with particular interests in the southern sky, accepted invitations to attend the symposium, together with twenty local delegates. The first week of the symposium (March 18–21) was held in Canberra and was devoted to galactic problems.

The proceedings began with an excellent review by J. H. Oort of our present knowledge of the large-scale structure of the Galaxy and of the many fundamental questions awaiting solution. Some of the major topics raised were the dynamics of the Galaxy, the structure, content and evolution of spiral arms, the distance to the galactic centre, the expansion of the gas found there, the nature of the galactic corona and the possible role of magnetic fields.

Many of the forty-nine papers presented concerned the concentration of different objects into spiral arms. Such concentrations are found for young galactic clusters (Becker), *O* and *B* stars (Petrie, Thackeray, Bok), long-period cepheids (Kraft and Schmidt), H II regions (Becker, Courtes), interstellar absorbing clouds (Thackeray), *A* stars (Lindblad, Bok) and early *M* stars (Westerlund). Objects of greater age—such as galactic clusters of spectral type later than *B*3, short-period cepheids, late *M* stars and planetary nebulæ (Perek)—show no concentration into arms, so that the life-time of a spiral feature appears to be of the order of 5×10^7 years. Detailed comparison of the distribution of objects of different ages promises to reveal the life-cycle of a spiral feature, and should indicate whether the stars disperse by their random motions or whether the motion of the gas differs systematically from the gravitational circular velocity. R. P. Kraft and M. Schmidt found that the older Cepheids tend to lie closer to the galactic centre than the Sun. As *OB* associations are found in greater numbers farther out than the Sun, there is the suggestion of an outward movement of the region of active star formation.

There was considerable discussion of the different locations of the H I concentrations within 3 or 4 kiloparsecs of the Sun and the segments of spiral arms delineated by optical indicators. The shape of the H I arms agrees roughly with those traced by the optical objects, and H. F. Weaver and others stressed that the disagreement in positions could arise in part from the use of photometric distances for stars and kinematic distances for H I regions. However, B. F. Burke reported a similar lack of correspondence for the southern part of *M*31. In his summarizing paper on galactic problems M. Schmidt gave a lucid exposition of the need for using similar methods for determining the distributions of objects before comparisons are made. He stressed the value of comparing longitude distributions quite apart from any distance

measures, particularly near tangential points. The strength of this method had been seen in the paper by B. J. Bok, showing the *OB* stars and clusters in the Carina arm clearly isolated in longitude, as B. Y. Mills found for the synchrotron emission. The longitude distribution is also a powerful means of delineating spiral structure from the 21-cm emission within the Sun's distance from the centre (Kerr).

An alternative comparison is that based directly on radial velocities, without resort to a rotational model to find distances. Cases were reported of good agreement between the velocities of H II regions, young stars and interstellar absorption lines (Courtes), between 21-cm absorption features and H II regions (Parijsky) and between 21-cm emission features and Ca II absorption lines (Thackeray). Another powerful, but little exploited, method is the ordering of objects in the line of sight by absorption measurements, both optical and radio.

There were a number of papers which increased confidence in the photometric distance scale. A. Blaauw's determination of the distance to the nearby Scorpio–Centaurus association gives an alternative method of finding the distance of the remote stars in H and χ Persei, and agrees within $\pm$ 0·27 magnitudes with the less-direct procedure starting from the Hyades. J. Graham also showed that H_β intensities yield excellent distances ($\pm$ 0·4 mag.) for *O* and early *B* stars, and could be applied to stars of 15 mag. using a telescope of only 50″ diameter.

The kinematic distances determined for H I concentrations rely heavily on our knowledge of galactic rotation and of the Sun's distance from the centre (R_0). The method will fail where there are large departures from circular motion. Maps of the neutral hydrogen spiral arms published by the Leyden and Sydney observers have been based on a value of the Oort constant *A* of 19·5 km/sec kiloparsec, and so a distance to the centre of 8·2 kiloparsec. For some time it has appeared that the photometric distance scale corresponds to an appreciably smaller value of *A*, and many separate determinations were discussed at the symposium. It seems probable that the value of *A* must be about 15 km/sec kiloparsec. Thus it is not surprising that large discrepancies are found between optical features and the published positions of the H I concentrations.

A new galactic rotation curve was presented by F. J. Kerr, based on high-resolution 21-cm measurements along the galactic equator. This confirmed the difference between the velocities for positive and negative longitudes indicated by broad beam surveys. The shape of the northern and southern velocity curves are found to be strikingly similar, suggesting that there are two major spiral arms or rings between the Sun and the centre, with a fine-structure that persists over a wide range of longitude. The north–south velocity asymmetry may reveal an outward motion of the material in the solar neighbourhood as previously suggested by Kerr. However, his latest results show that there is not a general expansion of the gas in the Galaxy, but that large-scale deviations from circular motion (up to 20 km/s) are present. R. M. Petrie's *B*-star velocities indicated strong local departures from circular motion, and a small outward motion of the material near the Sun. Non-circular motion over regions of 1 kiloparsec scale were also obvious in H. F. Weaver's discussion of the velocities of very-early-type stars.

The interpretation of the galactic rotation measurements depends on the solar motion. The accuracy of the standard solar motion was questioned by R. P. Kraft and M. Schmidt, and by O. J. Eggen.

Perhaps the most striking feature of the symposium was the wealth of information yielded by the large radio telescopes which are now in operation at Parkes in Australia, Green Bank in the United States and Nançay in France. F. J. Kerr's investigation of the galactic plane between $l^{II} = 60°$ and $l^{II} = -60°$ has already been mentioned. The work of B. F. Burke, K. C. Turner and M. H. Tuve between $l^{II} = 11°$ and $l^{II} = 50°$ also revealed the extreme complexity of structure of the H I spiral arms. These papers demonstrated that 21-cm investigations of the structure of the Galaxy are still in their infancy.

The high-resolution continuum measurements by E. R. Hill and M. M. Komesaroff at 1,410 Mc/s have yielded a notable improvement in our knowledge of radiation near the galactic plane. Many sources can be identified with H II regions in the *Mount Stromlo Atlas*. Many other sources previously regarded as extended are resolved into groups of discrete sources, which appear to be spread along spiral arms. It is striking that the distribution of the thermal radiation along the plane (for l^{II} between 280° and 354°) remains as a continuum background similar to that found with wide-beam surveys, rather than being resolved into many sources as found in the anticentre region. The very symmetrical distribution of the background thermal radiation about the centre agrees with the previous evidence for a ring of ionized hydrogen (or part thereof) 3·5 kiloparsec from the centre.

One of the challenging developments in radio astronomy has been the measurement of linear polarization of the galactic non-thermal (synchrotron) radiation. Measurements in Australia have confirmed the original Dutch observations of polarization in limited regions of the sky at 408 Mc/s. The recent measurements in Holland were reviewed by G. Westerhout. For polarized extragalactic sources at low galactic latitudes F. F. Gardner has measured considerable Faraday rotation, and a depolarization apparently associated with the fine structure in the electron distribution across the line of sight. These effects could explain the failure to observe polarized radiation from large areas of the galactic belt. For the regions where polarization is observed Gardner finds that the Faraday rotation is small, suggesting that they are very local.

There was only one paper on the fundamental subject of how the spiral structure of the galaxy persists. B. Lindblad demonstrated that the trailing arms produced by gravitational perturbations may become a quasi-steady formation by the circulation of matter between the outermost arms. This implies that the arms are quite massive and contain stars of population I of fairly high age, which calls for detailed investigation of the composition of a typical arm. Expectations that the spiral arms might be maintained against differential galactic rotation by hydromagnetic forces faded when R. D. Davies described the Zeeman splitting of 21-cm absorption features. Although the interpretation of the results was hotly debated, it became clear that the general galactic field is below 10^{-5} œrsted, too weak to resist the gravitational forces.

B. Y. Mills reviewed the evidence for the existence of a corona extending out to a radius of 10 kiloparsec from the centre. J. H. Oort reported observations of discrete H I clouds with large negative velocities at high latitudes, presumably located in the corona. The amount of gas in the corona might be 10 per cent of that in the galactic disk.

The second week of the symposium (March 25–28) was held in Sydney. The first day was devoted to the galactic centre, the majority of the papers discussing recent radio-astronomical measurements. A high-resolution survey at a wave-length of 10 cm by B. F. C. Cooper and R. M. Price showed the same complex of sources near the centre known from Drake's work at 3·75 cm. The central source appears to be mainly thermal in nature; the surrounding sources are partly non-thermal at 10 cm, the non-thermal emission becoming predominant at longer wave-lengths. This result was borne out by Y. N. Parijsky's observations at a number of wave-lengths between 3 and 33 cm. Considering the energy losses of relativistic particles Parijsky argued that the non-thermal emission and the gas flow from the centre are episodical in nature, arising from magneto-hydrodynamic instabilities.

J. H. Oort concluded that the neutral gas flow might be due to the explosion of a very large mass of gas in the galactic nucleus, if the 'explosion' lasted more than 50 million years. Oort's results showed that, despite the marked asymmetry of the gas distribution near the centre, almost equal masses of gas are found in the features in the south-east and north-west quadrants. B. F. Burke reported 21-cm observations over a wider range of longitude showing 3 or 4 distinct features in the moving gas near the centre, one being a branch on the 3 kiloparsec expanding arm. His measurements do not agree with a uniform expansion of the 3 kiloparsec arm. High resolution observations by F. J. Kerr show large H I density fluctuations along the 3 kiloparsec arm, the structure size being several hundred parsecs. Kerr's 21 cm absorption measurements show many small absorbing patches as well as the nearby hydrogen and the 3 kiloparsec arm. The rapidly rotating disk of Rougoor and Oort shows considerable fine structure. The only optical contribution to the session was G. Courtes' description of observations of H II regions near the centre with a high selectivity interference filter giving almost complete elimination of starlight.

The last three days of the symposium were devoted to the Magellanic Clouds, and were accompanied by far more active discussion of the twenty-nine papers than had marked the galactic sessions. In his introductory address, H. C. Arp pointed out that 66 per cent of galaxies may be dwarf galaxies like the Clouds, yet they contribute only about 0·3 per cent of the observed mass. Arp discussed the ways in which a double system like the Clouds might have evolved, the similarity of composition implied, and the possibility of a tenuous link between the Clouds and the Galaxy. The role of magnetic fields in the formation of the Clouds is most important, and calls for careful optical and radio measurements of polarization, particularly in the bar of the Large Cloud. The Clouds provide an unrivalled opportunity to locate the exact places where stars are now being formed.

The most striking results to emerge on the structure of the Clouds were the high resolution radio observations carried out in Australia. R. X. McGee showed that the neutral hydrogen in the Large Cloud can be resolved in position and radial velocity into many separate cloud complexes, on a low intensity background. The positions of these complexes correspond closely with H II regions and with young stellar associations. Some of the complexes have diameters over 500 pc, and masses up to 10^7 solar masses. Very little H I was found in the bar, in agreement with optical evidence that it contains a considerably older population than most other Large Cloud objects. In contrast with the H I complexes in the Large Magellanic Cloud, J. V. Hindman found only a few individual H I clouds in the Small Magellanic Cloud, loosely associated with H II regions. The gas is smoothly distributed over the main region of the Small Cloud, but shows a curious bifurcation in radial velocity. There appear to be five or six discrete gaseous bodies, two of them producing peaks in the 21-cm line profile separated by about 40 km/s. This suggests a large-scale separation of the components but, as pointed out by Oort, separation at such a low velocity could not last. Seeking an alternative explanation, Thackeray and Bolton suggested that self-absorption could produce the bifurcation, but this did not seem generally acceptable; Oort suggested that there is a complicated streaming of the gas in the system. A similar contrast was provided by G. Courtes' observations of H II regions, which had much filamentary structure in the Large Cloud and very regular distributions in the Small Cloud.

Radio continuum observations at 1,410 and 408 Mc/s were reported by D. S. Mathewson and J. R. Healey, showing that many discrete sources were present beside the 'background' radiation from the Clouds. In the Large Cloud 30 Doradus was very prominent and 90 per cent of the other discrete sources were shown to be thermal and identified with H II regions, many also corresponding to McGee's H I regions. One source in the Small Cloud was suggested as a supernova remnant.

B. E. Westerlund reported on the distribution of planetary nebulæ, of *M* stars and carbon stars detected with an infra-red objective prism, and of 400 clusters in the outer part of the Large Magellanic Cloud. The carbon stars show a tendency towards clustering and avoid regions of *OB* stars. Westerlund also found that the number of Wolf–Rayet stars in the Large Cloud is proportionally greater than in the Small Cloud or the Galaxy, about half occurring in associations. The distribution of these very young objects gives an important guide to the processes of stellar evolution in the Clouds.

The basic problem of the elimination of foreground stars of intermediate colour has been resolved by several different methods. Using objective prism techniques, Ch. Fehrenbach has identified more than a hundred members of the Large Cloud by their high radial velocities, although A. D. Thackeray pointed out that a few Population II stars in the Galaxy will have high reflected velocities and need to be eliminated by a luminosity classification. Sir Richard Woolley eliminated foreground stars by their proper motions determined from the chance discovery of a deep astrographic plate taken in 1912. Th. and J. H. Walraven have also had considerable success in identifying Cloud members by means of accurate multi-colour photometry. By such elimination of foreground stars meaningful colour-magnitude arrays can be obtained.

Colour-magnitude arrays were presented for a number of clusters in the Clouds. B. J. Bok discussed the isolated young association *NGC* 1929–37 in the Large Cloud, containing 97 stars with $M \leqslant -4{\cdot}0$ contributing 4,000 solar masses to a total mass of less than $2{\cdot}4 \times 10^4$ solar masses. The association contains much ionized hydrogen and is embedded in a concentration of neutral hydrogen. The total mass of H I is about 5×10^6 solar masses (McGee) and could give rise to several hundred more generations of bright stars. We may here find some of the vital answers to the problems of stellar formation. The deficiency of red supergiants or other evolved stars suggests that the association is not stable, but radial velocities are not yet available to check this. B. E. Westerlund investigated clusters such as *NGC* 602 in the 'wing' of the Small Cloud, finding that the wing is generally made up of clusters of blue stars. During a search for a second population in the Large Cloud Sir Richard Woolley found a faint open cluster of intermediate age, demonstrating the need for investigation of the numerous less-conspicuous clusters in the Clouds.

V. A. Ambartsumian suggested that 30 Doradus should be regarded as a 'super-association', a special class which he has found in a number of super-giant galaxies.

W. G. Tifft discussed the old-population stars found in the Small Cloud halo. The red cluster *NGC* 121 has a colour-magnitude array quite similar to that for galactic globular clusters, but stars of this age are rare in the Clouds. In the inner halo globular-like clusters such as *NGC* 419 of intermediate age are common. A. D. Thackeray commented on the dearth of RR Lyrae variables in Cloud clusters. S. C. B. Gascoigne discussed the colour-magnitude arrays for six red, globular-like clusters in the Clouds. All these contained bluer stars than are found in galactic globular clusters or in *NGC* 121, and most have ages of about 10^9 years. It appears that clusters of all ages are present, but that the main phase of star formation in the Clouds began much later than in the Galaxy.

Long-standing arguments about differences in the metal abundances of the brightest stars in the Galaxy and the Large Cloud were resolved during the symposium by work such as Feast's on *NGC* 330. Agreement was reached that the abundances are the same. D. J. Faulkner produced evidence that the helium/hydrogen ratio in Large and Small Cloud emission regions was 25 per cent

lower than in the solar neighbourhood, while L. H. Aller suggested that the oxygen/hydrogen and neon/hydrogen ratios were also slightly lower. The near equivalence of the element abundances in the Clouds and the Galaxy is somewhat surprising in view of the more advanced evolutionary state of the Galaxy.

S. C. B. Gascoigne presented observations of 14 Small Cloud Cepheids and 13 Large Cloud Cepheids. In the Small Cloud the slope of the period-luminosity relation is steeper than Arp's, while in the Large Cloud it is lower than that found by the observers at the Royal Greenwich Observatory. The small difference in slope might be due to a difference in reddening. It appears unlikely that the Small Cloud Cepheids are actually redder than those in the Galaxy.

M. W. Feast has derived a rotation curve for the Large Cloud from the radial velocities of 40 emission nebulæ. He finds that the position of the major axis agrees with that suggested by de Vaucouleurs, and that the rotation curve is close to that found for the inner regions from 21-cm measurements. There can be no doubt that the rotation centre lies 1° away from the centre of the bar, posing the problem of how the bar has been maintained despite differential rotation.

The symposium was closed by a thorough review of Magellanic Cloud problems by A. D. Thackeray, followed by a session of most active free discussion.

The publication of abstracts of papers before the symposium was one of the many activities of the organizing committee under B. J. Bok which contributed to the success of the symposium. The proceedings will be published at the end of the year by the Australian Academy of Science and the International Astronomical Union, and edited by F. J. Kerr and A. W. Rodgers.

Notable among the visits made during the symposium were those to the 210-ft. radio telescope operated by the Commonwealth Scientific and Industrial Research Organization at Parkes and the optical interferometer of the Universities of Sydney and Manchester at Narrabri. An aerial tour of inspection was made of the field station of Mount Stromlo Observatory on Siding Spring Mountain near Coonabarabran. Other visits were made to Mount Stromlo Observatory, the site of the University of Sydney's Mills Cross near Canberra and the Sydney Observatory.

The symposium was marked by the fruitful combination of radio and optical observations. It was fitting that it should have been held in Australia, where both these branches of astronomy are thriving. Many of the visitors were impressed by the number of young astronomers in the country, and stressed the need for a large optical telescope to assure the development of the subject, to complement the major radio telescopes and to exploit the astronomical potentialities of the Southern Milky Way and the Magellanic Clouds. STRATOSPHERIC PARTICLES AT 20 KM

By S. C. MOSSOP

C.S.I.R.O. Radiophysics Laboratory, Sydney

RECENT investigations by Junge *et al.*[1–3] have demonstrated the presence of a widespread, persistent layer of particles between altitudes 15 and 25 km. The maximum particle concentration, which occurs at about 20 km, was found to be approximately 0·1 per cm³ and varied only by a factor of 3 among the dozen or so measurements made at various times and latitudes. The particles range in diameter from about 4 to 0·2μ, the lower limit being set by collection methods used. The particles are hygroscopic and consist mainly of sulphate. The altitude distribution of the sulphate points to a stratospheric origin, and Junge suggests that it is formed by the action of ozone on sulphur-bearing gases carried up from the Earth's surface. He has shown that the stratospheric aerosol contains, in addition to sulphur, the elements aluminium, silicon, potassium, calcium and iron.

Friend and Sherwood[4] have found that more than 90 per cent of the total mass of the stratospheric aerosol consists of ammonium persulphate and ammonium sulphate. Eight collections at an altitude of 20 km yielded an average concentration of these particles of 1·1 per cm³ for diameters of 0·16μ and above, the variation being 0·1–3·6. These values depend heavily on extrapolation to the smallest sizes and may be in error by a factor of 5.

Because of this omnipresent layer of sulphate particles, Junge and Manson[3] point out the difficulty of detecting extra-terrestrial particles in this size-range, at altitudes below 25 km.

Higher-altitude collection has since been accomplished by Hemenway and Soberman[5], who report on the examination of micrometeorites recovered by a sounding rocket from heights of over 80 km. These particles they classify as spheres, irregular particles with rounded surfaces, and 'fluffy' irregular particles which appear to be aggregates of much smaller nodular particles each about 0·1μ diameter. Observed clusters of such smaller particles on the collecting surface suggest that some aggregates break up on impact. The particles examined by Hemenway and Soberman generally lie between 0·1 and 1μ diameter, though irregular particles up to 40μ in length are illustrated. A few results of analysis of particles are reported. It is also stated that 'fluffy' particles of about 1μ in greatest dimension have been found in collections made in the lower stratosphere from *U*-2 aircraft.

Particles collected at an altitude of 20 km over Australia by exposing electron-microscope grids covered with a nitrocellulose film in the airstream from a *U*-2 aircraft have been examined by the present author. These consist almost exclusively of hygroscopic particles of the size and concentration reported by Junge *et al.* A typical collection is illustrated in Fig. 1. It has been confirmed that ammonium sulphate is a major constituent of these particles. Within the aggregations of water-soluble material are small, dense, insoluble particles many of which are undoubtedly of extra-terrestrial origin. These are of such a size that most of them would escape collec-

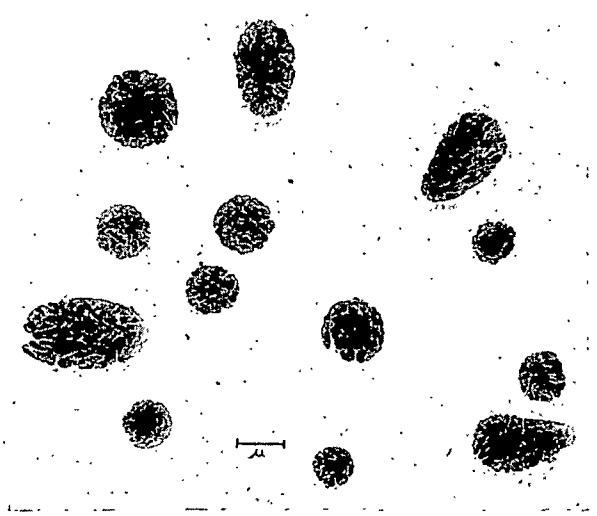

Fig. 1. Electron micrograph of atmospheric particles collected at an altitude of 20 km, February 13, 1963

tion if they were not encased in the much greater mass of sulphate.

In order to reveal these insoluble particles for examination it is first necessary to remove most of the soluble material by floating the specimen grids on purified water, collecting face upward. Dialysis for a suitable length of time leaves only the insolubles surrounded by a residual ring which establishes the position of the original material, as shown in Fig. 2. Occasional rings are devoid of insoluble particles; but as particles of the expected appearance are found on the film nearby, it is believed that each aggregate of soluble material contains at least one insoluble particle. This has been confirmed by exposing several collections of stratospheric particles to an intense electron beam: the sulphate evaporates, leaving behind at least one stable particle for each 'parent' particle.

The flattened shape of the parent particles leads one to believe that they must have been moist when collected: impact occasionally gives rise to a ring of small satellite particles round each main one. The insoluble particles presumably assist the nucleation of the soluble solids which are deposited on them from gaseous reactions. In rare cases the soluble deposit is thin enough for the enclosed dense particles to be visible without dialysis: an example is shown in Fig. 3. This represents a case where the insoluble particles have had a comparatively short sojourn between 15 and 25 km.

Eight collections of particles made at 20 km between latitudes of 20° and 45° S. over the period January–May, 1963, show concentrations of parent particles varying only from 0·04 to 0·09 per cm³ with an average of 0·06. These values are corrected for the theoretical collection efficiency of the sampling probe.

The insoluble particles left behind after dialysis fall into the following categories:

(1) Electron-dense, irregular particles with nodular surfaces. The particles in Fig. 3 are of this type.

(2) Highly irregular, less electron-dense particles which resemble, in all but size, the 'fluffy' particles of Hemenway and Soberman. Their appearance is consistent with formation by the break-up of such aggregates.

(3) Electron-dense spheres and spheroids of diameters 0·5–4μ were found in the collection of May 7, 1963.

Fig. 2. Residue after dialysis of water-soluble material from collection of January 31, 1963

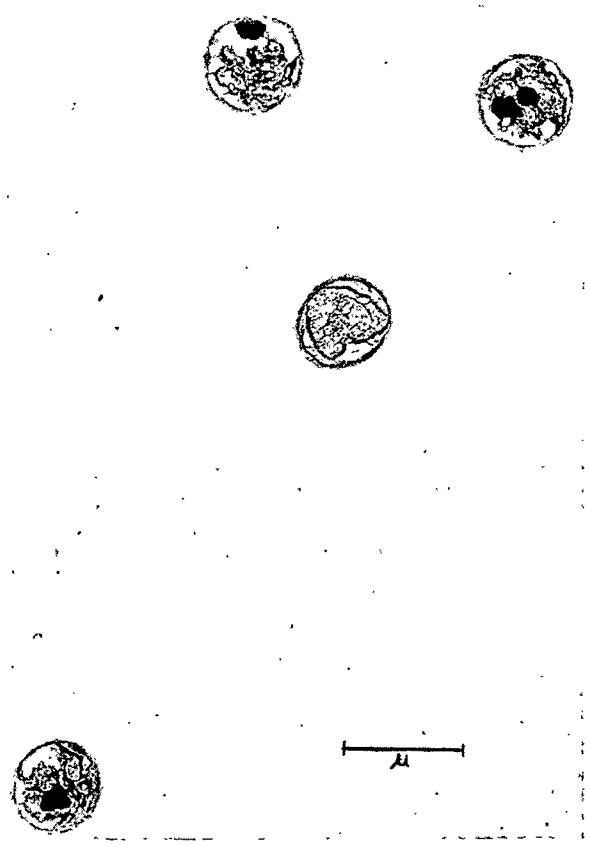

Fig. 3. Particles collected on March 12, 1963, in which denser inclusions are visible even without dialysis

(4) The collection of April 11, 1963, and subsequent collections contain comparatively large angular particles quite different in appearance to the usual types of insoluble particles present. These are undoubtedly volcanic dust from the eruption of Mount Agung, Bali, on March 17. The southward progression of vivid sunsets after the eruption and their persistence, point to the presence of considerable quantities of volcanic dust in the stratosphere at the time and place of these collections.

From the similarity in appearance of particles in categories 1–3 to those found by Hemenway and Soberman above 80 km, it is thought likely that they are extraterrestrial in origin. The particles of the first two categories range in size from 0·02 to 0·5μ with a median value of 0·08. The number found within each soluble particle may be as high as 8, but the average appears fairly constant from one occasion to another at about 2. It thus appears that the average concentration of such particles at an altitude of 20 km is at least 0·1 per cm³. This refers only to those particles which have sojourned at altitudes below about 25 km long enough to grow by deposition of sulphates to a diameter greater than 0·1μ, the theoretical cut-off limit for the collection system used. To collect smaller, newly arrived particles it is obviously necessary to sample well above 25 km.

I thank the personnel of *O.L.*11, 4080th Strategic Reconnaissance Wing, U.S. Air Force, for carrying and operating the particle-sampling apparatus on their aircraft. I also thank the Sydney University Electron Microscopy Unit for electron microscopy and in particular Mr. C. Shorey for his assistance.

FACTORS DETERMINING THE BEHAVIOUR OF PLANT PATHOGENS IN SOIL

AN international symposium on factors determining the behaviour of plant pathogens in soil, sponsored by the Agricultural Board of the National Academy of Sciences—National Research Council and supported by grants from the National Institutes of Health, National Science Foundation and Agricultural Research Service, was held during April 7–13, at the University of California, Berkeley.

The symposium was organized by W. C. Snyder (chairman), K. F. Baker (co-chairman), R. R. Baker, F. E. Clark, A. W. Dimock, W. A. Kreutzer, J. D. Menzies, L. I. Miller and Z. A. Patrick. There were 35 invited papers, and 300 active workers in this field were asked to participate in the meetings.

Fungi, bacteria, viruses and nematodes, either free-living or dependent on plant roots and stems in soil, cause plant diseases resulting in enormous annual losses in food production. Control of these diseases has been pursued, using a variety of biological and chemical methods with some outstanding successes. 'Take all' of wheat caused by the fungus *Ophiobolus graminis*, once a major threat in most wheat-growing areas of the world, is effectively controlled by rotation of crops. 'Wilt' diseases of many crops caused by the *Fusarium* fungus are partly controlled by crop management and the use of resistant varieties. 'Bunt' of wheat is now almost completely controlled by pretreating seed with chemicals before planting. *Phymatotrichum* root rot of cotton, 'scab' of potato, *Sclerotium* rot of peanut, and diseases of several important tropical crops are being successfully controlled by regulating the activity of the pathogens through manipulation of the organic matter in soil.

These and the many other effective controls already established have been developed, partly by empirical testing methods, but based on an understanding of the behaviour of the causal organisms in soil in relation to the host plants. However, for many important soil-borne diseases affecting the world's crops there is still no satisfactory method of control. Empirical testing of control methods has either failed or resulted in a baffling mixture of success and failure at different times or in different places.

Basic investigations on the behaviour of micro-organisms in soil has expanded rapidly in the past twenty-five years. Concomitant with this expansion, both as cause and effect, is the growing understanding of the soil as a complex environment in which the biological entities, the higher plants, soil microflora and fauna interact with each other and with the physical and chemical factors. Thus for the plant pathologist interested ultimately in the control of economic diseases, important information is now forthcoming, not only from his own basic studies on disease organisms, but also from the fields of plant anatomy and plant physiology, biochemistry, soil physics, soil chemistry, genetics and soil microbiology.

This symposium brought together for the first time leading workers in these fields in a most successful attempt to integrate the present information, to determine the most promising new approaches to biological control of diseases and to define the more important areas in which investigations were urgently needed.

S. D. Garrett sketched the broad background of the symposium in the introductory paper, "Toward Biological Control of Soil-Borne Plant Pathogens". He outlined the broad patterns for decreasing the population or activity of pathogens in soil by introduction of antagonistic micro-organisms to soil, or the modification of the soil environment by the use of added organic matter, the growing of particular crops or selective chemical and physical treatments. He discussed in detail the necessity for critical experimentation on, and analysis of, the present views on soil populations and the factors influencing them.

The remaining papers of the symposium may be considered in four sections.

The six papers following Garrett by A. N. Burges, D. K. McE. Kevan, J. H. Warcup, J. M. Hirst, D. Park and A. S. Sussman dealt with the present background knowledge of the soil microflora and fauna, their distribution, growth and survival. Kevan's comprehensive coverage of the soil microfauna disclosed our ignorance of the relation between these animals and the general soil microflora, but he suggested there may be some possibility of nematode control by other members of the soil fauna.

Burges and Warcup were complementary in that, while both of them stressed the importance of methods for population determination, the former dealt in detail with the complicated ecological succession involving fungi, bacteria and animals in specific situations in soil. Warcup discussed the broad range of fungi occurring in soils, stressing particularly groups such as the Basidiomycetes which had not been adequately sampled by previous methods, and he then considered the activity of the organisms in relation to substrate. Hirst's discussion of dispersal of soil micro-organisms emphasized the neglected evidence that they do disperse, but in the majority of cases at a very slow rate. His broad approach will undoubtedly stimulate more precise experimentation along these lines and his discussion of the importance of resting structures in relation to dispersal in time effectively linked his paper with those of Park on survival and Sussman on dormancy. These last-named speakers surveyed the known factors such as antibiosis, competition for nutrients and adverse soil physical or chemical effects on survival structures of organisms, and the importance of dormancy in these same structures.

The second section of the symposium, consisting of papers by W. A. Raney, H. D. Chapman, Flora M. Scott, H. Burström, A. D. Rovira, H. Katznelson and D. J. D. Nicholas, dealt with the influence of physical and chemical factors of the soil and the presence of higher plants on the microbiological population. Physical factors outlined by Raney have scarcely been investigated for their influence on soil micro-organisms although there are abundant suggestions of their importance in the plant pathology literature. There is more detailed evidence of the influence of chemical factors to the point of partial control of a disease such as *Thielaviopsis* root rot of citrus. The detailed papers by Scott on root anatomy and Burström on root physiology brought most of the symposium participants to a common meeting ground for the first time. The rationalization of root structure and function with each other and with the evidence on root exudates and root infection provided a lively debate. Rovira and Katznelson discussed in detail the nature of the root exudates and their influence on soil micro-organisms, particularly bacteria. Their presentations led to considerable discussion on the importance of these phenomena and the use of model systems in their further investigation. Nicholas extended the incidental remarks of the two previous speakers in a discussion of the rhizosphere influence on plant nutrition in which he considered the supply of and competition for many minerals by both the micro-organisms and the higher plants.

The third section of the symposium, with papers by J. L. Harley, C. H. Cadman, N. T. Flentje, I. W. Budden-

hagen, W. B. Mountain, J. C. Walker, I. A. M. Cruickshank and P. S. Nutman, dealt with host infection, mechanisms of pathogenesis and host resistance. Cadman reviewed the present knowledge of fungi and nematodes as virus vectors and put forward tentative groupings of the soil-borne viruses in relation to either their known or probable characteristics. Mountain comprehensively reviewed the present knowledge on nematode infection of higher plants and subsequent mechanisms of pathogenesis. Nutman, in a detailed discussion of *Rhizobium* legume symbiosis, outlined the mechanism of root-hair invasion by the bacteria and indicated different stages where the invasion or subsequent symbiosis breaks down; he postulated physiological reasons for the breakdown.

Harley and Flentje discussed the infection of plants by fungi and the contrasts between mycorrhizal fungi causing little destruction of host tissue and the recognized pathogens where enzymatic attack or metabolite toxicity causes death or serious malfunction of host tissue. Buddenhagen extended the discussions by the earlier speakers in this section on the evolution of pathogenicity and presented a stimulating discussion of population dynamics of bacteria in relation to survival in soil and spread from one host to another. Walker, in his discussion of disease resistance, reminded the symposium that while we have long-standing examples of disease resistance we still have not found any basic pattern linking mechanisms of pathogenesis with the genetic information on resistance. Cruickshank, however, in discussing the role of phytoalexins, suggested that antifungal materials formed by hosts in response to infection may be an important aspect of disease resistance.

The final section, consisting of papers by F. E. Clark, R. A. Fox, R. M. Jackson, M. G. Boosalis, R. Mankau, R. R. Baker, A. E. Dimond and J. G. Horsfall, Mary D. Glynne, Z. A. Patrick and T. A. Toussoun, T. S. Sadasivan, R. A. Ludwig, G. W. F. Sewell, W. A. Kreutzer and S. Wilhelm, dealt with a range of factors influencing the population of saprophytes and pathogens in soil and the use of these factors in biological control of disease.

Clark outlined the possible factors in soil making for competition between organisms, urging much clearer thinking about the concept of competition. Jackson dealt with the general question of antibiosis in soil, suggesting there was strong presumptive evidence for antibiosis as a factor in competition, but indicating there was still no clear picture of the origin of antibiotics in soil or the factors influencing their presence. Boosalis and Mankau stressed the fact that while parasitism and predation between micro-organisms is well known in laboratory culture there is still little direct information on its occurrence in natural soil. Baker and Dimond linked these discussions on antagonism with their consideration of 'inoculum potential'. Inoculum potential is not a static concept of population of an organism but a dynamic concept of population, biological energy and infectivity. Dimond and Horsfall set out a mathematical basis for estimating the several aspects of inoculum potential.

Fox and Mary Glynne discussed the severity of diseases in Malaya and Britain in relation to long-term crop management, where in both instances disease control has been effective. The associated microbiological investigations in each case are giving new insight into the reasons for these successes. Patrick and Toussoun presented evidence that organic residues so often regarded as beneficial by increasing antagonism of other organisms to pathogens can often be harmful because of toxic materials produced. Ludwig described similar effects from the use of chemicals in soil which in some cases had been dramatically successful but in other cases made the position worse. Kreutzer carried this analysis further, indicating that soil in which most of the organisms were killed was an excellent substrate for re-colonization by potential pathogens, suggesting the most effective treatment was one specific for the particular pathogen. Sadasivan dealt with the effects of mineral nutrition on disease control and presented some interesting results from the use of foliar application of different minerals. Sewell emphasized the fact that although temperature effects on soil organisms and disease were well known because they were easy to study, the effects of oxygen/carbon dioxide relations and other factors were probably of equal importance in influencing pathogen population and activity in soil.

Wilhelm concluded the formal papers with a comprehensive analysis of the biological balance in natural soil. He stressed the fact that the microbial complexity of soil maintains a natural balance which keeps a wide range of disease organisms in check. Our primary task is to swing further the balance against disease organisms.

The formal review of each day's papers by J. D. Menzies, A. Kerr, J. E. DeVay, G. C. Papavizas and A. W. Dimock gave a valuable progressive synthesis of the discussions.

There are sufficient examples of successful biological control of diseases to indicate that concentrated basic investigations in this field would yield important economic results. But there are important gaps in our knowledge that frustrate our present attempts to achieve this. These gaps became obvious during the symposium discussions.

Our knowledge of the soil microflora and fauna is still fragmentary, limited on one hand by the inadequate techniques so far developed and on the other by the immensity of the task. We must, as a basis for much of our future work, intensify our general ecological studies on the soil micro-organisms.

Microbial competition in soil was a question dominating much of the symposium discussions. Is it competition for oxygen, water, space, nutrient supply, or is it escape from or resistance to antibiotics? Clark's provocative analysis went almost unchallenged because the present research fragments are insufficient to make an informative picture. Yet this is one major prop to the working concept of biological control. How can we systematically and effectively increase competition by addition of organisms to soil, by alteration of the physical or chemical factors of the soil unless we clearly define the nature of such competition?

The host plant as a factor influencing the chemical environment of the soil or as a substrate for infection was also a dominating feature of the conference. Extensive debate on the detailed physiology and anatomy of roots, the nature of the root surface, the detail of secondary root emergence revealed our needs for further information on critical aspects. Composition of root exudates is now well documented and there was strong opinion that our future studies in this field should be directed into two main channels. What components of root exudates are most active in influencing the sections of the microflora antagonistic to pathogens? What components of root exudates directly influence the infection of roots by pathogens? There is already evidence that foliar sprays and other treatments can influence root exudates and this line of investigation holds considerable promise for disease control. Such investigations are already meeting other investigations on the detailed analysis of plant infection in relation to the anatomy and physiology of the root. The place of model systems in such investigations was warmly debated, the crux of the debate being the relation between an artificial model system and the natural conditions in the soil, a further reflexion of our present fragmentary knowledge of the ecology of soil organisms and the influence of chemical and physical factors in the soil.

Throughout the symposium the variability of the soil micro-organisms continually intruded into discussion. How applicable are experimental results with one race of an organism to another race? Where such races have been recognized and defined the problems are recognized, but this represents the minority of cases. Wider recognition of race differences in relation to survival in soil and

pathogenicity to different hosts, investigation of the responsible mechanisms of variation and the background genetics of these organisms is essential.

The vigorous discussions during the symposium will undoubtedly influence programmes of work already in progress and shape the framework of much of the future planning. This was its purpose and the indications are that it was eminently successful. Equally, certainly it encouraged our hope for significant extension of the already successful biological control of plant diseases.

The benefit and encouragement from this symposium was expressed in a resolution, endorsed unanimously by the participants: "that a second symposium, along somewhat similar lines, should be held possibly in Britain, in five years time". A steering committee was selected at the symposium to investigate this possibility.

The proceedings of the symposium, including papers, session reviews and general discussion will be published in full. The volume should serve as a valuable reference text in this field. N. T. FLENTJE

TEACHING OF BIOLOGY

AN interim report of the Royal Society—Institute of Biology Joint Committee on the Teaching of Biology has recently been issued.

The Committee has made itself acquainted with a large amount of work being carried out by numerous bodies at present interesting themselves in the improvement of biological teaching.

It feels strongly that biology should not be taught solely as a vocational training, but should take its proper place as a powerful instrument of education for life in the modern world. It has taken particular note of the Biology Section of the Nuffield Foundation's Science Teaching project and its work in devising teaching aids for the age-range 11–16.

Biology in the Sixth Form: University Entrance. The Committee has been informed of the views of professors of botany and zoology on desirable qualifications for entrance to university biology departments. A majority of each expresses a preference for a combination of biology and chemistry at the Advanced Level of the General Certificate of Education with supporting qualifications in physics and mathematics. A willingness to accept other combinations has been indicated, and the more traditional one of botany, zoology and chemistry is preferred by a minority. The Committee agrees that means should be devised to secure the maintenance of a minority stream of 'natural history' biologists through the universities.

Biology Syllabuses. In accordance with the trend already noted many examining bodies are at present producing or revising syllabuses for biology as a single subject at advanced level. The Committee notes with regret that no co-ordination has been attempted between the different examining bodies and that needlessly wide divergencies are arising which will create serious difficulties for sixth-form biology teaching

Relations between Sixth Form and University Biology Teaching. The connexion between school and university teaching is the weakest link in the present chain. It requires careful study with a close co-ordination of the views of those engaged on both school and university aspects of the problem. The Committee proposes to set up a small study-group to obtain the necessary data which should enable it to make proposals within a reasonable time for a rational solution of this critical problem.

Teachers' Refresher Courses. Individual university biology departments, usually with the co-operation of departments of education, have provided valuable help to school teachers in the form of vacation courses of about a week's duration. These have been well supported and much appreciated; but it is thought that not more than 10 per cent of the demand is at present met. To satisfy the demand fully would place an unmanageable burden on the university departments. It has been suggested that university and technical college departments should be asked to provide short (one-day or week-end) courses for teachers from schools in their own neighbourhoods. A sampling inquiry to about a dozen departments has shown much willingness on their part to co-operate. The Committee therefore proposes to circularize biology departments in universities and technical colleges throughout the country with the hope of promoting a nation-wide network of such help for teachers.

Curriculum Studies. A panel of the Joint Committee met and discussed the American Biological Sciences Curriculum Study courses with a number of educationists who have recently visited American schools.

As a result of their discussions it is not felt possible to adapt these courses to British conditions, both because of the considerable differences of suitable biological material, and because of the great divergences of the American and British educational systems into which the biology has to be fitted. The publications associated with the courses are being sent to Britain, and may have their uses as teachers' source books (see *Nature*, **197**, 4; 1963). It does not seem necessary either to encourage or to discourage their entry.

A pamphlet setting out the aims of the Biological Sciences Curriculum Study project and its relevance to British conditions is being prepared and will be published in the Institute of Biology Journal.

Pamphlets on Current Topics. The Committee has welcomed a proposal from the Institute of Biology to publish on a subscription basis a series of booklets on subjects of biological interest yet falling outside the normal text-book range or up-to-dateness. It has undertaken to advise on the choice of topics and a number of titles are under consideration.

OBITUARIES

Prof. F. W. Jane

THE sudden death of Prof. Frank W. Jane on May 6 in Ibadan where, with the permission of the Council of Royal Holloway College, he was acting as temporary professor and head of the Department of Botany in the University of Ibadan, leaves a gap which is going to be very hard to fill. Indeed, because he was such a modest man, it is only now that one realizes in how many different spheres he had achieved distinction and how widely he will be missed.

First and foremost he was a botanist and naturalist. Much of his early research work, while he was at University College as assistant lecturer, lecturer and then reader, dealt with freshwater algae. The results were published between 1937 and 1944 in such journals as the *Transactions of the Hertfordshire Natural History Society* (1937, 1938,

1939), the *New Phytologist* (1941, 1944) and the *Journal of the Royal Microscopical Society* (1944). These include detailed descriptions of *Pteromonas varians*, *Cyclonexis erinus* and *Chlororhabdion diogenes* (all new species) and a revision of the genus *Harpochytrium*. They are a tribute to his excellent microscopy and meticulous technique and brought him the award of a D.Sc. in 1944. Although recently he had little time for active research on algae, his interest in it remained. There was generally at least one research student in the Department of Botany at Royal Holloway College working on an algal topic under his supervision, most recently in relation to the growth of algae in reservoirs. This led to a grant from the Department of Scientific and Industrial Research to promote such research and a close connexion with the Metropolitan Water Board.

From 1949, when he was appointed to the chair of botany at Royal Holloway College (University of London), much of his time and energy went on administration and in work on timber and trees. His book, *The Structure of Wood*, published by Black in 1955 and which he had almost finished revising, is the most authoritative treatment of the subject. It is used not only by academic students but also by students of timber technology. Indeed, he was one of the country's leading authorities on trees. Coupled with his fair-mindedness and impartial judgment this gave him the standing of an expert in lawsuits involving trees and timber and brought him much advisory work on tree management in estates and towns. He had a close connexion with the Institute of Wood Science and the Timber Research and Development Association.

The Botanical Supply Unit of the University of London, started in 1950 at Englefield Green, owes a great deal to his vision and drive. Under his wise chairmanship it has expanded from three to twenty acres and is now a Botanic Garden in which he will long be remembered and one of which the University may justly feel proud.

It was as a naturalist, ornithologist and photographer that Jane spent any leisure he allowed himself, and to his students and colleagues he was a delightful and inspiring companion on any field excursion. It is characteristic of him that here too he made himself an expert. Among other things, he served on the Field Studies Council, had been president of the School Nature Union and the Essex Field Club and was chairman of the local Committee of management of Blakeney Point for the National Trust. In the new booklet of Blakeney and Scolt Head, about to be issued, he was responsible for the sections on Birds, Flowering Plants and Ecology. He was a perfectionist in his photography and used his own coloured slides to illustrate the many stimulating talks he gave to biological and natural history societies throughout the country.

From the age of fifteen, when he left school, he had to work to earn his academic education and he took his degree as a part-time student at Birkbeck College. It was perhaps the memory of these early days that made him so sympathetic to anyone who wanted to learn and gave him such a practical interest in education at all levels. As chief examiner and later moderator in the advanced level of the General Certificate of Education in botany he was able to influence the teaching of botany and biology in schools. He was similarly involved in biological education at training colleges and was particularly interested in the problems raised by the expansion of their course from two to three years. He did invaluable work in planning the training of science laboratory technicians, among whom he numbered some of his personal friends. He was a vice-president and former president of the Institute of Science Technology as well as chairman of the University of London Committee on the Training of Technicians. Unlike some professors, he was always ready to encourage and supervise part-time research students. He will be remembered in Africa particularly for his services to the Departments of Botany of those overseas colleges in special relation with the University of London to which he paid many visits and gave much advice. Their appreciation is summed up by one of them in a letter which says his loss will be felt in no fewer than six of the developing countries, and that it is perhaps symbolic that he should have died in Africa.

His untimely death at the age of sixty-two, at the height of his powers, will be mourned by the many people who have benefited from his help and encouragement. We extend our sympathy to his wife and daughter.

Margaret A. P. Madge

Dr. H. S. Holden, C.B.E.

After graduating with honours in botany from the University of Manchester, H. S. Holden was appointed a lecturer and demonstrator in botany in University College, Nottingham, in 1909. At that time the College occupied buildings in Shakespeare Street. Even in those early days, Harry Holden was a stimulating personality. He initiated and directed vigorous research work in the Department. He was a gifted exponent and, looking back, it seems quite natural that he should have taken an active part in the Workers' Educational Association Extension courses run by and from the College.

He always had a deep interest in micro-organisms and during the First World War served as bacteriologist at the Plymouth Naval Hospital. On his return to University College, Nottingham, he took up his general teaching duties and the advancement of research work. His own particular interests lay in the field of plant anatomy and in microbiology, and this dual interest is reflected in the range of work on the anatomy of plants, on fungi, and on bacteria which came from the Department in subsequent years.

About 1921 he was awarded the degree of D.Sc. of the University of Manchester for work on seedling structure. In 1927 he was appointed senior lecturer in botany and head of the Sub-Department of Industrial Bacteriology. In the years preceding 1928 plans were made to build at Highfields a new University College, and Holden assumed much of the responsibility for the planning of the Department of Biology. On the retirement of Prof. Carr, Holden was appointed head of the Department of Biology in 1928. The growth of this Department in subsequent years and increases in the staff resulted in the re-alignment of Holden's duties, and in 1932 he became professor of botany and head of the Biology Department, and finally in 1934 professor of botany and head of the Botany Department.

His early anatomical studies led him to an interest in palæobotany, particularly of Coal Measure plants, and he collaborated with Dr. D. H. Scott in a series of anatomical studies of fossil plants. He was responsible for the purchase by the University College of the D. H. Scott collection of reprints, which consists of a wide range of pamphlets dealing with all branches of botany.

Holden was a man of great enthusiasm, blessed with an enquiring mind which led him into paths not at that time recognized as the precincts of botanists or biologists. Thus, he was consulted on various occasions by local police authorities in connexion with cases of water pollution. His wide knowledge of microscopy and of plant structure, even in its most minute details, led quite naturally it seems now to the development of applied microscopy and of scientific methods in the solution of crime. His early teaching experience in Nottingham was in the old College in Shakespeare Street. This may have been a portent of the future, because when the East Midland Forensic Science Laboratory was established in 1936 he became its first director. This Laboratory finally occupied well-planned and well-equipped premises in Shakespeare Street, not far from the old College. I believe this Laboratory was the first of its kind in the country, and it is not surprising that some ten years

[redacted]he Forensic Science Service, Holden [redacted]f the Metropolitan Police Laboratory [redacted] Yard.

[redacted]his interest in micro-organisms, it was [redacted]al that even when he became director of [redacted] Science Laboratories in Nottingham he still [redacted] contacts with industrial firms in the neigh- [redacted] and with the discovery of the importance of [redacted]n the early years of the War he was instru- [redacted] bringing together in a Nottingham laboratory [redacted]onsiderable collection of cultures of species of [redacted]*um*.

[redacted]ve vivid recollections of my first meeting with [redacted] Holden in the Department of Botany, University [redacted]asgow, round about 1923. On that day he was sitting [redacted]e assistants' room inking in drawings of a fossil stem [redacted]n the Kidston collection. I was captivated by the [redacted]eness of his draftsmanship, and by the speed with [redacted]hich he worked. He kept up a running fire of com- [redacted]mentary during the whole of the period, and I had a foretaste then of what has remained with me as an abiding memory of Dr. Holden, his immense vitality and deep interest in botany, and his rare genius for communicating with anyone his unbounded enthusiasm. He was a man who could not tolerate inactivity and slackness and who spent his energies in the service of biology, particularly of botany, without stint. He was gifted with considerable organizing ability, and was quick to see and to seize advantages in situations as they presented themselves.

There can be no doubt that Holden exemplified scientific versatility to an amazing degree. His success in the forensic science field bears witness to this, but after a long and active career in this service it gave pleasure to many of his friends that he returned to his palæobotany studies in the last few years of his life, and brought to these the same enthusiasm and vigour which so marked him in his days in the Department of Botany, University College, Nottingham.

C. G. C. CHESTERS

NEWS and VIEWS

Biochemistry at Sheffield: Prof. W. Bartley

DR. W. BARTLEY, who has been appointed to succeed Prof. Quentin H. Gibson in the chair of biochemistry at the University of Sheffield (see *Nature*, 198, 939; 1963), returns to the University where he graduated in 1950 with first-class honours in physiology. In the same year he joined the Cell Metabolism Research Unit of the Medical Research Council in the Department of Biochemistry at Sheffield, and in 1954, on the appointment of the director of the Unit, Prof. H. A. (now Sir Hans) Krebs, to the Whitley professorship of biochemistry at Oxford, he moved with the Unit to the Biochemistry Department at Oxford. In 1959 he transferred to the staff of the Oxford Biochemistry Department as a University demonstrator. His main research interests concern the biochemistry of mitochondria, a field in which he has made important contributions distinguished by careful and systematic experimentation. His interests include the elucidation of the part played by lipids in structure and function in living cells, and generally the relations between structure and biochemical function. He has built up a reputation as an enthusiastic undergraduate and postgraduate teacher who may confidently be expected to add to the distinguished record of the Biochemistry Department at Sheffield.

The 1963 Guggenheim International Astronautics Award: Prof. M. Nicolet

PROF. MARCEL NICOLET, director of the Centre National de Recherches de l'Espace in Belgium, has been awarded the 1963 Daniel and Florence Guggenheim International Astronautics Award. The Award, which carries with it a prize of 1,000 dollars, is offered annually to an individual who has made outstanding contributions to the progress of astronautics during the preceding five years. Prof. Nicolet is well known for his achievements in the fields of aeronomy and planetary atmospheres. He was the first to point out correctly the effect of sunlight and diffusion in modifying the composition of the upper atmospheres of Earth and planets. This work enabled him to predict in the planetary upper-atmospheres the existence of a helium belt which was later shown by space probes to be correct. He was awarded the Triennial Prize of the Agathon De Potter Foundation of the Belgian Royal Academy of Sciences and became a member of the Academy in 1962. For seven years he was secretary-general of the Special Committee of the International Geophysical Year.

The Nuclear Science and Engineering Corporation, Pittsburgh, Pa.

Mr. Francis S. McMichael and Mr. Frank G. Chambers have been elected to the Board of Directors of the Nuclear Science and Engineering Corporation.

F. S. McMichael

Mr. Francis S. McMichael is a vice-president of Mellon National Bank and Trust Co. He is a director of the Jeannette Glass Co., the Keystone Box Co., South Hills Ornamental Iron Co., Division of Mulach Steel Corporation and the Pryce Machine and Manufacturing Co. He is also a member of the Allegheny County Bar Association, the American Society of Planning Officials, the Pennsylvania Planning Association and the Mt. Lebanon Planning Commission.

F. G. Chambers

Mr. Frank G. Chambers is president and a director of the Continental Capital Corporation, a small business investment corporation in San Francisco. He is chairman of the Board of Hazleton-Nuclear Science Corporation, the western affiliate of the Nuclear Science and Engineering Corporation. He is also a director of Maydwell and Hartzell, Guardian Paper Co., Kimball Manufacturing Co. and the *Journal of Commercial Art*. He served as director of the Office of Priorities and Controls, Munitions Board of the U.S. Defense Department.

The Nuclear Science and Engineering Corporation was formed in Pittsburgh, Pa., immediately after passage of the Atomic Energy Act of 1954. It conducts research and development, utilizing nuclear and radioactive tracer techniques on production and research problems of industry and Government. It also provides specialized radioactivity and radiation measurement services, and is considered a leading producer of radioactive isotopes. The four technical departments of the firm include physical sciences, biomedical isotope applications, radiation biology and radioactive materials.

The Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme : Awards

AWARDS under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made as follows: Dr. M. Adhikari, lecturer in applied chemistry, University of Calcutta, to enable him to work on physico-chemical properties of clays and clay membranes at the Imperial College of Science and Technology, London, from July to December 1963; Dr. A. K. Chandra, lec-

turer in chemistry, University of Calcutta, to enable him to carry out research in quantum chemistry at the Mathematical Institute, University of Oxford, for six months from October 1963; Prof. J. N. Chatterjea, professor of organic chemistry, Patna University, to enable him to study fungal metabolites at the School of Pharmacy, London, for six months from September 1963; Dr. E. U. Emovon, lecturer in chemistry, University of Ibadan, to assist him to learn further techniques in gas phase kinetics and photochemistry at the University College of Wales, Aberystwyth, for six months in 1963; Dr. D. M. Moore, lecturer in botany, University of Leicester, to assist him to visit the Falkland Islands and possibly South Georgia for about three months from January 1964 to collect flowering plants there, in connexion with a study of evolutionary and phytogeographical relationships of circum-Atlantic floras; Dr. H. M. Pantin, geologist at the New Zealand Oceanographic Institute, Wellington, to assist him to investigate the small-scale internal structures of marine sediments from the New Zealand area and from the region of the British Isles, at Bristol, for a year from October 1963; Prof. W. G. Spector, professor of pathology, St. Bartholomew's Hospital Medical College, to enable him to carry out an electron microscopic study of certain aspects of the inflammatory reaction, at the University of Melbourne, for three months from December 1963; Dr. C. W. Stearn, associate professor of geological sciences, McGill University, Montreal, to assist him to visit the United Kingdom during February–April 1964, for an examination of Nicholson's collection of Stromatoporoids in the British Museum; Dr. J. R. Turvey, lecturer in chemistry, University College of North Wales, Bangor, to enable him to study new techniques for investigating the structures of glycoproteins at Queen's University, Kingston, Ontario, from July to September 1963; Dr. E. H. Wright, lecturer in chemistry, Fourah Bay College, University College of Sierra Leone, to enable him to study recent developments in surface chemistry at the University of Bristol for three months from September 1963.

The Paul Instrument Fund Award

THE Paul Instrument Fund Committee has made grants as follows: £7,485 and £7,836 to Prof. H. M. Barlow, Pender professor of electrical engineering, University College, London, (i) for the development of a microwave electrostatic wattmeter, and (ii) for the construction of instruments for the measurement of electrical power at very high frequencies by the absorption of the angular momentum of a circularly polarized wave; £4,970 to Prof. P. B. Moon, Poynting professor of physics in the University of Birmingham, for the construction of a linear motion gamma-ray spectrometer; £3,000 to Dr. G. Munday, lecturer in chemical engineering and chemical technology, Imperial College of Science and Technology, London, for the design and construction of a camera having frame rates up to 200,000 p.p.s., capable of synchronization and being a true framing device having automatic shutter facilities, to be used for further experiments on the dynamic deflexion of disks; £950 to Mr. K. G. Nichols, lecturer in electronics, University of Southampton, for the construction of apparatus giving an improved method for the vacuum deposition of thin films of high melting-point materials; £1,800 to Dr. E. E. Schneider, reader in solid state physics, King's College, Newcastle upon Tyne, for the development of superconducting cavities for use in magnetic resonance spectrometers; £730, as a supplementary grant, to Dr. P. M. B. Walker, lecturer in zoology, University of Edinburgh, for the improvement of the microspectrophotometer which he constructed by means of previous grants amounting to £9,730. The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Institute of Physics and the Physical Society and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British research workers in Great Britain f design, construction and maintenance or much improved types of physical i apparatus for investigations in pure or ap science".

The Australian Marine Sciences Association

THE inaugural meeting of the Australi Sciences Association was held at Cronulla, N Wales, on May 18 and was attended by 43 o founder members. The objects of the Associa "to promote the marine sciences in Australia provide for the exchange of ideas and information b those concerned with marine science". It was a that ordinary membership should consist of "pe who are or have been engaged in research in a branc marine science and such other persons who seek mem ship whom the Council deems could contribute to t objects of the Association". The first Council of th Association consists of: *President*, Dr. G. L. Kesteven; *Vice-President*, Prof. W. Stephenson; *Secretary*, Dr. J. M. Thomson; *Treasurer*, Dr. J. C. Yaldwyn; *Councillors*, Miss J. Hope MacPherson, Dr. E. P. Hodgkin and Dr. H. B. S. Womersley.

At the associated congress held on May 19 the following papers were presented: G. F. Humphrey, "The Organization of the C.S.I.R.O. Division of Fisheries and Oceanography"; H. B. Wisely, "Fouling Tests and the Rearing of Pelagic Larvæ"; D. J. Tranter, "Zooplankton Abundance in Australian Waters"; D. Vaux, "Fisheries Hydrology in South-eastern Australia"; J. P. Robins, "Water Type Preference of Tuna"; G. L. Kesteven, "Marine Stock Assessment"; J. M. Thomson, "Counting Salmon"; W. G. H. Maxwell, "A Review of Marine Geological Research in Australia"; H. B. S. Womersley, "A Review of Marine Botanical Research in Australia"; J. T. Baker, "The Chemistry of Some Marine Purple Pigments"; D. F. McMichael, "The Australian Museum's Swains Reef Expedition".

Further information concerning the Association can be obtained from the Secretary at P.O. Box 21, Cronulla, New South Wales.

The Arthur D. Little Research Institute

THE annual report for 1962 of the Arthur D. Little Research Institute records a broadening of activities in physics, including initiation of a basic study of the interface between metals and molten glass, and re-orientation of the work of the High Polymer Group, whose work has been primarily concerned with the crystallization behaviour of polymers with the view of obtaining control of the structure and properties of the final product (Pp. 44. Inveresk, Midlothian: Arthur D. Little Research Institute. 1963). Reduction in spherulite size in a given sample of polyethylene on cooling from the melt has been achieved through the discovery of the process of 'seeded' crystallization. An investigation has also been initiated into the mechano-chemical modification of co-polymers. The biochemical and biophysical work on glutens has pointed to interesting properties of gluten-based films, and work has commenced on the utilization of humic acids from peat and anti-tubercular factors in milk whey. New techniques have been devised for preparing 'tailor-made' polyamides and an investigation commenced on carrageenan, the mixture of water-extractable polysaccharide sulphates of certain species of red seaweeds. Investigations continued on the chemical modification of wood and the emission of corrosive volatiles from wood, as well as the chemical modification of cotton fabric to give increased crease-resistance. The nature of the impurities which cause spontaneous polymerization of ethylene sulphide has been determined, and when these impurities are avoided ethylene sulphide has been kept at room temperature for six weeks without deterioration. Work

continued on its reaction with amines and with mercaptans. Investigations in the hydrogen embrittlement of certain steels continued, and also of the reaction between molten aluminium and water vapour. The total staff at December 31, 1962, was 51, including 25 graduates, and a list of publications is included.

Employment of Graduates

THE annual report of the University of Birmingham Appointments Board for the year ended December 31, 1962, records a more selective attitude from employers (Pp. 6. Birmingham: The University, 1963). However, the anxiety of many firms not to become inbred is regarded as having prevented a squeeze on graduates with low honours or pass degrees, and competition is regarded as undoubtedly growing at this end of the academic scale. Of the 804 who obtained first degrees in 1962, 762 registered, of whom 413 men and 33 women were in science, compared with 407 and 37, respectively, in 1961. Of the graduates in science and technology, 6·3 per cent took teacher training and 2·3 per cent teaching posts in schools. Of 199 men who obtained first degrees in science in 1961–62, 83 took up research work or further academic study at home and 6 overseas, 30 teacher training and 70 gained employment by December 1962; for 113 with higher degrees the corresponding figures are: 18, 22, 2 and 51; for 214 men with first degrees in technology, the corresponding figures are: 63, 4, 4, and 127; and of 123 with higher degrees in technology, 7 took up research work or further academic study at home and 72 had gained employment by December 1962.

The Carnegie Institution of Washington

A MOST attractive illustrated brochure issued by the Carnegie Institution of Washington describes concisely but clearly some of the achievements during the past sixty years of the Mount Wilson and Palomar Observatories, the Geophysical Laboratory, the Department of Terrestrial Magnetism, the Department of Plant Biology, the Department of Embryology, and of the Genetics Research Unit. The brochure shows very clearly the character of the Institution's work, which is now concentrated mainly in three broad fields: the form, contents and dynamics of the universe; the structure and evolution of the Earth; and the frontiers of biology (Pp. 20. Washington, D.C.: Carnegie Institution of Washington, 1963).

The Transvaal Museum, Pretoria

IN their annual report for 1962, the Board of Trustees of the Transvaal Museum, Pretoria, still trust that the recommendations of the two commissions of inquiry will be implemented (Pp. 38. Pretoria: Transvaal Museum, 1963). They deplore the present unsatisfactory circumstances both with regard to the Museum in general and the Cultural History Division in particular. Both the finance and space requirements are inadequate. The Museum was instrumental in promoting the Namib Desert Research Station Project. During the year, five large habitat-groups were completed, namely, sable, waterbuck, koedoe, mountain zebra and crocodile. Considerable additions have been made to the study collections, including several new and rare forms, especially among the insects. Some alleviation in the storage of large mammals and historical material was made possible by the renting of two storerooms outside the precincts of the Museum.

Role of Microbiologists in Underdeveloped Countries

IN a speech delivered last November to the American Society of Microbiology on the role of microbiologists in assistance programmes for underdeveloped nations, and now printed in the *Journal of the Washington Academy of Sciences* (April 1963), Dr. C. Lamanna makes three recommendations regarding the contribution of microbiologists, and illustrates their significance by describing briefly the results achieved by such an approach to the control of diarrhœal diseases in the Philippines. First, he recommends that the allocation of resources and the direction of the efforts of microbiologists should fit into a general scheme of balanced activities, aimed at raising living standards as a whole, including efforts to reduce barriers to change and to raise the economic resources of the community. Secondly, he stresses the need to reduce the cost of microbiological activities, both by simplification and the use of local substitutes for imported material where possible. Thirdly, the microbiological research programmes in these countries should evolve by natural progression from efforts to meet practical needs. In this way the social value of microbiology would be demonstrated and the microbiologist himself would be required to accept his social responsibilities.

Microbial Classification

ARRANGEMENTS are being made by the Canadian Committee on Culture Collections (in collaboration with the Numerical Taxonomy Sub-committee of the International Association of Microbiological Societies) to hold a Summer School Conference on Microbial Classification in late August or early September, 1964. Strong emphasis will be placed on the numerical taxonomy of bacteria, and most of the time will be given to discussion of focal topics, including theory and practice of microbial classification, data-processing methods, computers, and implications for culture collections and nomenclature. Further details can be obtained from Dr. C. Quadling, National Research Council of Canada, Sussex Drive, Ottawa 2, Ontario.

Radioisotopes and Ionizing Radiations in Entomology

No. 9 in the bibliographical series published by the International Atomic Energy Agency, Vienna, is divided into two main sections dealing respectively with radioisotopes and ionizing radiations, and their uses in entomology; and there is a short section concerned with nematodes in agriculture (*Radioisotopes and Ionizing Radiations in Entomology*. Pp. 414. Vienna: International Atomic Energy Agency; London: H.M.S.O., 1963. 168 Schillings; 48*s*.; 8 dollars; 32 N.F.; 28 D.M.). The references are arranged under authors' names in alphabetical order within each topic; the topics include ecology, physiology and biochemistry, insecticidal studies, practical applications in control, techniques, etc. Each reference is accompanied by an abstract of the contents. Data on special subjects, such as dispersal and flight range, radiation sterilization, metabolism of insecticides, have been brought together in a series of tables in the appendix. An index to authors and a very detailed subject index are included. The period covered is 1950–60 (very few papers had been published before 1950) and the coverage must be almost complete. As a piece of bibliographical work it is well done (the compilation is by Mrs. M. Binggeli) and well produced. It is, of course, illogical to divide a science on the basis of a technique—but it may be none the less useful for that.

The Department of Geology at the University of the Panjab

A REPORT by Prof. N. R. Martin on the establishment of the Department of Geology at the University of the Panjab, West Pakistan, 1952–62, under the expanded programme of technical assistance, which has recently been published by the United Nations Educational, Scientific and Technical Organization, summarizes the work of the Technical Assistance Mission in establishing this Department, to which contributions were made under the Colombo Plan, from the Leverhulme Trust Fund and by the British Council, as well as by Unesco. The number of agencies which participated in this project is one of the features of the whole project and it is also noteworthy

that it took a full decade to complete. The staff, headed by a professor, includes three readers, five lecturers, five student demonstrators and two technicians, a secretary, clerk and library clerk, with four laboratory assistants and others bringing the total to 30, with a departmental expenditure for 1961–62 estimated at 765,882 rupees. Some 83 students have already graduated as B.Sc. and 49 as M.Sc., and a research programme has now been established. There is a real need for geologists in Pakistan, and the Mission was consistently supported by the Government of Pakistan as well as by Unesco, and was given as much freedom as possible by the University to build and administer the Department. Further expansion is recommended over the next two years by the establishment of a fourth readership (in structural and applied geology), a new lectureship (for hydrogeology), expansion of analytical facilities in the mineralogy section and of laboratory facilities in the applied geophysics section. The Department should be kept as a fully integrated department for at least five years, but by 1950 should be appraised with the view of raising the main sections to departmental status. Concentration until 1968 of all geological studies for the degrees of M.Sc. and Ph.D. work at the Panjab University is also recommended, and further assistance with overseas staff under an aid programme is regarded as unnecessary.

Farm Buildings Research

The first supplement, 1958–61, of Part 3, *Buildings for Poultry*, issued by the Agricultural Research Council, has recently been published (Pp. 71. London: Agricultural Research Council, 1963. 4*s*.). This bibliography of farm buildings research provides important basic information: in the past, much waste has occurred from the provision of unsuitable and uneconomic housing. Over-emphasis on one or another feature can lead to unsatisfactory accommodation and the disease situation is often below par on this account. With insufficient attention to the temperature requirements, to the general comfort of the occupants, etc., costs of ill-health may more than balance economies in management. Abstracts are given of 300 publications dealing with one or other of the important factors that require consideration in the planning of buildings. An indexed summary covers thirty major items, such as watering, nesting and humidity requirements of fowls, turkeys, ducks and geese.

Announcements

Dr. Charles Wilcocks, formerly director of the Bureau of Hygiene and Tropical Diseases, London, has been elected president of the Royal Society of Tropical Medicine and Hygiene in succession to Sir George McRobert.

The International Association of Forensic Toxicologists was formed during the conference on "Legal Medicine, Pathology and Toxicology", held in London in April 1963. The aims of the Association are to promote co-operation and co-ordination of effort among the members and to encourage research in chemical toxicology. The president is Dr. E. G. C. Clarke, and application forms for membership can be obtained from the secretary, Dr. A. S. Curry, 32 Rutland Drive, Harrogate.

A conference on "Metabolism and Physiological Significance of Lipids" will be held in Cambridge during September 15–21. Further information can be obtained from Dr. R. M. C. Dawson, Biochemistry Department, Institute of Animal Physiology, Babraham, Cambridge.

A general discussion on "Fundamental Processes in Radiation Chemistry", arranged by the Faraday Society, will be held in the University of Notre Dame, Indiana, during September 2–4. Further information can be obtained from the Assistant Secretary, the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

A conference, arranged by the Research and Industrial Applications Sections of the Royal Statistical Society, will be held in the University of Southampton during September 14–16. Further information can be obtained from the Secretary, Royal Statistical Society, 21 Bentinck Street, London, W.1.

An international conference on "Microwaves, Circuit Theory and Information Theory" will be held in Tokyo during September 7–11, 1964. The conference is being organized by the Institute of Electrical Communication Engineers of Japan. Further information can be obtained from Dr. Kiyoski Morita, c/o The Institute of Electrical Communication Engineers of Japan, 2–8 Fujimicho, Chiyoda-ku, Tokyo.

A symposium on "Modern Instrumentation in Science and Industry", organized by the London Branch of the Institute of Biology, the London Section of the Royal Institute of Chemistry and the London Branch of the Institute of Physics and the Physical Society, will be held at the Institution of Electrical Engineers on January 17, 1964. Further information can be obtained from the Honorary Secretary, Institute of Biology, 41 Queen's Gate, London, S.W.7.

A colloquium on "The Optics of Solid Thin Layers" is being organized by the Commission Internationale d'Optique and will be held in Marseilles during September 8–15. Subjects under consideration will include: theory of solid thin layers; preparation of layers; structure and optical properties; optical applications. Further information can be obtained from Prof. P. Rouard, Faculté des Sciences, place Victor-Hugo, Marseille 3.

A summer school in "Molecular Biology" will be held in Ravello during September 2–15. Subjects covered by the School will include: the physicochemical methods of studying biological macromolecules; structure, function and biosynthesis of nucleic acids and proteins; mechanism of enzymatic reactions; quantum theory of biochemical structures and reactions. The School will be followed by a symposium on "The Electronic Aspects of Biochemistry", to be held during September 16–18. Further information can be obtained from Prof. B. Pullman, Institut de Biologie Physico-Chimique, 13 rue Pierre Curie, Paris 5.

A conference on "The Liquid State", arranged by the Institute of Physics and the Physical Society, will be held at the Imperial College of Science and Technology, London, during September 9–13. The conference will be divided into four main sections: structure and excitation spectra; equilibrium properties, including simple mixtures and solutions, evaporation and solidification; transport and dissipative processes and fluctuations; electronic properties. Further information can be obtained from the Administrative Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

The fifth international congress on "The Stratigraphy and Geology of the Carboniferous", arranged by Charbonnages de France, will be held in Paris during September 9–12. Subjects under consideration will include: stratigraphy and palæontology; sedimentology, petrography, geochemistry; coal petrography; the microflora of the Palæozoic; the microfauna and its applications to the stratigraphy of the Carboniferous; special geological problems. Further information can be obtained from the General Secretariat, Fifth International Congress on the Stratigraphy and Geology of the Carboniferous, Charbonnages de France, 9 avenue Percier, Boîte Postale, 396–08, Paris 8.

Erratum. In Table 1 of the communication entitled "Progestational Activity of 4-Hydroxy-17-Alpha-Acetoxyprogesterone" by Prof. G. Sala *et al.*, which appears on p. 262 of the January 19 issue of *Nature*, steroid No. 6 should be 9β-10α-pregna-4,6-dien-3,20-dione.

NEW DEVELOPMENT IN UNIVERSITY EXTRAMURAL WORK

THE report of the Universities Council for Adult Education, 1961–62, entitled *New Development in University Extramural Work**, prepared by Mr. A. Parker, director of Extramural Studies, University of Birmingham, is based on the reports of the extramural departments of the universities of the United Kingdom for 1961–62 and on additional information supplied by them. It raises again, at the outset, the question whether the new variety and extent of extramural work was entirely mere opportunism, but Mr. Parker suggests that the past seven years have been formative and that a new pattern is emerging. He considers that diversity between the different forms of course that have become established parts of extramural programmes—the day-release classes, the post-graduate courses, the provision for vocational groups, and work with industry—is less apparent than some years ago. Moreover, he feels that the underlying unity is to be sought in the distinctive kind of teaching that extramural departments should provide.

Several departments have directed attention to an increasing tendency for extramural work to mirror the range of intramural work of universities, and this might provide a simple answer to the question as to the distinctive characteristics of extramural teaching. While Mr. Parker suggests that extramural departments may sometimes be able to make a special contribution to courses arranged in co-operation with university departments of technology, he suggests further that the traditional concern of extramural departments with liberal studies has not diminished in importance. However, it would seem that liberal studies are not necessarily promoted by the traditional means nor necessarily differentiated sharply from professional studies.

If it is accepted that extramural teaching should be of a distinctive kind, it should also follow that this teaching should be open to all adults who are capable of profiting from such teaching. The three-year tutorial class was designed to meet a particular need, and, despite the decline in the number of such classes, in many places it still exemplifies the best extramural teaching. It should be asked, however, whether the spirit of the tutorial class may be preserved in new forms of course designed to meet contemporary needs, and Mr. Parker comments on the remarkable response at times in recent years from industrial workers, both in terms of quality and quantity.

Beyond this, Mr. Parker directs attention to the needs of a new group—the applicants with two or more Advanced-level General Certificate of Education subjects—for whom university places cannot be found, and asks whether traditional policies towards providing extramural courses leading to examination should be revised. He recognizes that extramural courses could not provide a substitute for intramural courses, but points out that, if considered as an adjunct to some of the many proposals for meeting unsatisfied demand for university places, they could provide at least occasional contact between students and good university teachers. Curiously enough, even in this context, the possible contribution or participation of the colleges of technology does not appear to be visualized. Moreover, while Mr. Parker recognizes that some extension of the principle of external degrees may be implied, he does not consider what might be implied in the suggestion of a new kind of external degree examination, specially designed to test the particular abilities of mature students who have the advantages, as well as the disadvantages, of alternating study with employment.

The report also includes a section by Mr. M. Bruce on the work of the Council's Sub-Committee on Broadcasting, set up in 1960, including its comments on the Government's White Paper on the Pilkington Report. The general expansion of programmes is welcomed, and educational programmes for adults are defined as programmes (other than school broadcasts) arranged in series and planned in consultation with appropriate educational bodies to help viewers towards the progressive mastery or understanding of some skill or body of knowledge. This definition is held to include programmes primarily designed for class use, for example, in technical colleges or centres for adult education, as well as those primarily designed for the viewer at home.

THE C.S.I.R.O. ANIMAL RESEARCH LABORATORIES

THE annual report of the Commonwealth Scientific and Industrial Research Organization Animal Research Laboratories for 1961–62* continues the accounts of much important research work covering a wide variety of conditions and of great importance to other countries. It outlines the work of three divisions dealing with animal genetics, animal health and animal physiology.

Apart from original work relating primarily to Australian conditions there are outstanding examples of the complementary value of work in Australia in the elucidation of important disease problems in many countries. Examples are the 'race', run off in 'heats' nearly half a century ago, on botulism research; the production of infective and toxic mixed culture after years of research from cases of 'lamsiekte' in cattle in South Africa; the discovery that a similar disease of animals in Australia was actually botulism; the triumph of technique in South Africa that enabled pure cultures of the organism to be made; the finding that the basic cause of the condition in that country was deficiency of phosphorus in the soil that led to depraved appetite with bone-chewing. The growth from this work of the importance of other mineral deficiencies that lead to ill-health in farm animals, Australia taking a share in these developments, was a striking development of the decades prior to the Second World War.

The importance of studies in general animal physiology was realized in certain of the newer countries earlier than in Britain, and, possibly with the less-entrenched and organized seats of learning, such work began to receive recognition in these countries at least a decade earlier. With the incentive of utilizing the great areas of potential animal country that is often of less obvious quality than the animal production areas of the old world, plus an open-minded outlook towards such developments, the enthusiasm and enterprise shown has paid large dividends. Work from Australia under the influence of the Commonwealth Scientific and Industrial Research Organization

* *C.S.I.R.O. Animal Research Laboratories.* Annual Report 1961–1962. Pp. 177 (mimeographed). (Melbourne: Commonwealth Scientific and Industrial Research Organization, 1962.)

has consistently proved the value of its policies. The range of genetics research reported runs from purely scientific work on *Drosophila* to studies of the myxomatosis virus, physiology of the coat in cattle concerning sweat glands and hair, to hybrid vigour.

Infective and non-infective diseases important to Australia and disease related to worm and arthropod infestation receive great attention. The geographical position of Australia has provided a great freedom from some of the devastating diseases of other countries with comparable climatic conditions and wise policy has enabled the position, all round, to be maintained. There are great risks of diseases introduced in the processes of commerce. The important work on bovine contagious pleuro-pneumonia, solidly entrenched in northern parts of the continent for a very long time, is continued. The special climatic conditions of the continent have great influence on animal husbandry, and physiological investigations into the means of obtaining the best possible results by attention to the production and management of animals that can thrive and be suitably exploited have been extensively carried out.

PRIORITIES OF HUMAN RESPONSIBILITY

THE following statement of policy concerning "Priorities of Human Responsibility" was issued after the fourth meeting of the International Trustees of the World Wildlife Fund which was held in Switzerland recently:

"The World Wildlife Fund believes that man has responsibilities of trusteeship for the natural world over which we now exercise such sweeping power. How do these responsibilities equate with other human responsibilities? The ending of all forms of human suffering is clearly of paramount importance. We must never waver in the fight against disease, hunger, the threat of war and every other kind of disaster and human misery. We must strive to make a world worth living in for everyone; but is a world without wildlife and wild places worth living in? Even when mankind is free from want and fear, will our children's grandchildren thank us if we have sealed off great wild areas of the earth from the Sun with bricks and mortar, concrete and plastics? Will they have to ask 'What was a wild animal?' or 'What was a wild place?'.

"When there is an unavoidable collision between the survival of man and the survival of wildlife, human interests must clearly prevail. It is our thesis, however, that such collisions are rare—that in most cases a little thought, ingenuity and good will can permit the co-existence of man and wildlife without which man himself is so much the poorer. Most of the species exterminated by man in historical times need not have become extinct and would not have done so if anyone had bothered about it. The survival of the dodo and the great auk would not have impeded human progress in the slightest degree.

"Thus the Fund's campaign is not a case of animals versus man. Conservation is for man, for the long-term benefit of humanity, and to ignore it is short-sighted and improvident. There is a close link between medical science and natural science, and an even closer link between the achievement of freedom from hunger and the conservation of wildlife, because both have to do with the proper use of the land and its priceless treasures.

"But there are also responsibilities for adding something constructive and uplifting to human lives as well as for saving them—responsibilities which in the field of conservation, grow daily more urgent, for the wild creatures cannot protest, and once a species becomes extinct nothing can re-create it. Ultimately, therefore, the concern of the World Wildlife Fund is with the future benefit of man and the spiritual enrichment of his life."

THE INTERNATIONAL EPIZOOTICS BUREAU, PARIS

THE report* for 1961–62 by the director, Dr. R. Vittoz, of the International Epizootics Bureau, Paris, made at the thirtieth annual conference, covers incidence of world-wide disease.

The Bureau functions through officials of the countries represented on its council and has a permanent staff in its Paris Office. Reports of its conferences are published in considerable detail and bulletins are issued giving statistical information supplied to that office. From time to time special conferences are called, in addition to the regular seasonal meetings, when particular internationally important problems arise, such as, for example, the break-out of African horse-sickness from the endemic regions in Africa in quite recent years, with great extension from the Middle East into Pakistan, India, and beyond. There is close association for relevant purposes with other international bodies such as the World Health Organization and the Food and Agriculture Organization of the United Nations. Collectively, these bodies are able to take most satisfactory action in emergency and, according to circumstances, also in the preparation of short- or long-term plans.

The functions and organizations of these bodies each strengthen the value of the others. Their knowledge of local conditions and circumstances everywhere is very good and detailed, and, with the help of the several countries, rapid and efficient action can be taken when required, experts and materials being mobilized and concentrated to the best advantage.

Many examples could be given of the manner in which the functions of the Bureau and of the other organizations with which it works have been utilized. During their existence there have been dangerous extensions of animal disease into countries previously free and, if early and effective action had not been available, losses from devastating disease would undoubtedly have been carried even further than was the case, with very serious results to countries with valuable livestock industries.

With the rapid extension of air transport within the memory of serving officials of all countries, and the risks of the possibilities that may arise from space travel in the future, the dangers of infective disease are far greater than in the past. Diseases that the veterinarian had considered to be comfortably tucked away in Africa and limited to that continent have caused very serious losses within the experience of the present working generation of experts. While known to be of the utmost importance to their endemic areas there had been little fear that their interest would be more than academic to workers elsewhere. Blue-tongue of sheep has invaded the United States and at great cost; African swine fever—quite a different virus to the unfortunately well-known scourge of most countries—has invaded the Iberian Peninsula and Mediterranean countries.

* Report for 1961–62 of the International Epizootics Bureau. Pp. 94. (Paris: Office International des Épizootics, 1962.)

As a result of the activities of these international bodies the serious problems posed by foot-and-mouth disease have been mutually assessed by the countries most nervous about its depredations, and also by the countries, less nervous, but fearing the dangerous possibility that inefficient control measures might permit extensions. An exotic and dangerous type of the virus has penetrated southern European countries and great endeavours are being made co-operatively to prevent its arrival in Western Europe.

The diseases at present causing most concern because of the difficulties about their control are dealt with in this report in great detail, region by region. Where wide-scale vaccination is useful and local means are insufficient, much effort is concentrated on the provision of materials and skilled assistance. W. A. Pool

INTERSTITIAL SOLID SOLUTIONS IN BODY-CENTRED CUBE METALS

By Dr. J. STRINGER and A. R. ROSENFIELD*

Department of Metallurgy, University of Liverpool

THERE is a well-known correlation between the activation energy for self-diffusion ΔH and the melting-point T_m for body-centred cube (b.c.c.) metals[1]:

$$\Delta H(\text{eV/atom}) \approx \frac{3T_m \text{ (deg K)}}{2{,}000} \quad (1)$$

The linearity of this relation arises because the activation energy is required to overcome the binding energy for the ring of atoms through which the diffusing atom has to move. Consider, for example, an atom diffusing from one cube centre to a vacant position at the centre of the adjacent cube. If the lattice parameter is a_0, the hard-sphere atom diameter is $0{\cdot}866\ a_0$, and the tunnel between the four atoms at the corners of the cube face through which the diffusing atom has to move has an inscribed diameter of $0{\cdot}548\ a_0$. During the movement, therefore, the four atoms at the face corners are displaced from their equilibrium positions by an amount $0{\cdot}159\ a_0$. The melting-point is related directly to the binding force between atoms, and thus ΔH increases with T_m.

In general, the activation energy of any solid-state diffusion process for which the rate-determining step is the displacement of matrix atoms will increase with the melting-point of the matrix element and, irrespective of the form of the functional relationship between ΔH and T_m, one boundary condition is:

$$\Delta H = 0 \text{ when } T_m = 0 \quad (2)$$

However, when the activation energy for the interstitial diffusion of oxygen, nitrogen, or carbon in b.c.c. metals is plotted as a function of the melting-point of the solvent (Figs. 1–3), a linear relation analogous to equation (1) is obtained only for those interstitials that exhibit low solubility; those with solubilities greater than about 1 per cent[2] exhibit little variation of ΔH with T_m. Thus:

$$\Delta H = \alpha(x)T_m \text{ for interstitials with small solubility} \quad (3)$$

and:

$$\Delta H = \beta(x)T_m + \gamma \text{ for interstitials with large solubility} \quad (4)$$

In these equations, the values of α, β and γ depend only on the interstitial considered, and in general $\beta < \alpha$. It is interesting to note that recent investigations of diffusion of substitutional atoms in f.c.c. metals show that the activation energy depends markedly on solubility[3,4] although qualitatively the effects are different.

Cottrell[5] has shown that the diffusion coefficient can be calculated from the Portevin–Le Chatelier effect by means of the equation:

$$D_T = 10^{-9}\dot{\varepsilon} \quad (5)$$

where $\dot{\varepsilon}$ is the strain rate at the temperature T at which the effect appears. Since D_0 is always about 10^{-2} cm^2 sec^{-1} for diffusion of interstitials in b.c.c. metals and strain rates used experimentally are generally close to 10^{-4} sec^{-1}:

$$\Delta H = 25{\cdot}3\ kT \quad (6)$$

where k is Boltzmann's constant. The general validity of equation (5) has been demonstrated by Mincher and Sheely[6] and others. Table 1 shows values of ΔH calculated from equation (6). These values, included as squares in Figs. 1–3, agree very well with the values predicted by equations (3) and (4), demonstrating the usefulness of Portevin–Le Chatelier data for predicting activation energies of diffusion for systems for which no direct measurements are available.

Table 1. Calculation of Activation Energies using the Cottrell Equation

Metal	Blue brittleness temperature °C	Ref.	ΔH eV/atom	Interstitial
Cr	300	24	1·26	C
Cr	475	25	1·64	O
W	950	26	2·70	O

The oxygen solubility in a number of transition-metal alloys is related to the electron/atom (e/a) ratio. With $e/a < 5{\cdot}7$, oxygen is soluble, and with $e/a > 5{\cdot}7$ oxygen is insoluble in a range of niobium alloys[7]. Jones *et al.*[8] have shown that the magnetic susceptibility of a number of transition-metal alloys is a minimum at an electron/atom ratio of approximately 5·7, and suggest that either the d-band is split or the density of states curve in the d-band shows a marked minimum at this electron/atom ratio. Bryant[7] has suggested that the vanishing solubility at this concentration can be accounted for on the basis of a Jones–Hume-Rothery mechanism, in which the development of the Fermi surface into a region of k-space in which the density of states is rapidly falling encourages the appearance of a new phase. This explanation is not altogether satisfactory in this case because it fails to explain why oxygen is insoluble in b.c.c. alloys with e/a in excess of 5·7, when the density of states is presumably rising again. This model predicts a solubility minimum at $e/a \simeq 5{\cdot}7$, but not a vanishing solubility at higher concentrations. On the basis of the model, Bryant suggested that oxygen is present as a positive ion in niobium, but this conclusion must be discounted.

The largest inscribed sphere which can be accommodated in the b.c.c. lattice is situated at positions of the type (0, 1/2, 1/4), and is in contact with the four atoms at the positions 0, 0, 0; 0, 1, 0; 1/2, 1/2, 1/2; and $-1/2$, 1/2, 1/2. These form a distorted tetrahedron, and the inscribed sphere has a radius of 0·1260 a_0, where, as before, a_0 is the lattice parameter. A sphere of this size would not, however, be very tightly bound, since the path to the adjacent site has a minimum radius of 0·0973 a_0, and the diffusion of an atom of exactly the right size would involve a displacement of three atoms by only 0·0287 a_0. There is also a site centred at 0, 1/2, 1/2 in the distorted octahedron formed by the atoms at 0, 0, 0; 0, 0, 1; 0, 1, 0; 0, 1, 1; 1/2, 1/2, 1/2; and $-1/2$, 1/2, 1/2. This site has a very small inscribed sphere, radius 0·0670 a_0, but it has a large volume: for example, a cylinder thickness 0·134 a_0 and diameter 0·548 a_0 can be accommodated, having a volume approximately five times that of the inscribed sphere in the tetrahedral site. In addition, diffusion of an ion having these dimensions would be relatively difficult, involving a movement of two matrix atoms through 0·207 a_0. From consideration of the crystallography of the martensite transformation, it is usually assumed that, in iron, carbon is located in these octahedral sites.

It follows from this geometrical analysis that, at least in those b.c.c. elements in which solubility is fairly high, the interstitial solute is most probably on the octahedral site and is not spherical, but lenticular or toroidal. It is difficult to discuss, even in semi-quantitative terms, the shape of ions in metallic solutions, but it seems likely that the saturated ions such as O^{--} have spherical symmetry. It is also likely that ions having half-full shells, such as O^{+}, will have spherical symmetry, although in this case there are other possibilities. In the free atom the three $2p$ orbitals are at right angles, so that, for example, an ion with four electrons in the p shell might have a configuration in which two of the p states are full and one is empty. The charge distribution would in this case be toroidal. It is also possible that one of the orbitals would be full and the other two half full, in which case the charge distribution would be cigar-shaped. In the case of an ion with five electrons to be accommodated in this shell, the charge distribution will be lenticular. Since the solvent has cubic symmetry, it seems unlikely that, at least for ions in the octahedral sites, the geometry of the orbitals will be very much affected by the matrix, although for these solute elements the possibility of (sp) hybridization forming a tetrahedral arrangement of orbitals cannot be overlooked.

In the free atom the $2p$ state is 6-fold degenerate, but since the octahedral site has only one 4-fold rotation axis, the presence of the lattice field will partly remove the degeneracy, producing a splitting of the levels. On symmetry grounds it can be inferred that the new levels will consist of one 4-fold degenerate level and two non-degenerate higher levels, associated with the p-state parallel to the 4-fold axis. It is, however, possible in the case of large ions that the 4-fold level may split into two doubly degenerate levels, each symmetrical with respect to the 4-fold axis of symmetry. The actual degree of filling of these levels will depend on their position relative to the Fermi surface in the solvent. If all the levels are below the Fermi surface a large spherical ion will be formed that would be expected on geometric grounds to have very low solubility.

On this basis it is possible to suggest an explanation for the dependence of oxygen solubility on electron concentration. For low e/a the highest level at least is above the Fermi surface and consequently unoccupied, producing an ion which can be accommodated in the octahedral site. However, at an electron-to-atom ratio of about 5·7 there is a minimum in the density-of-states curve so that the Fermi surface expands rapidly as the electron concentration increases, submerging the highest level and producing the large insoluble spherical saturated ion. This model successfully explains the disappearance of the solubility and accounts for its coincidence with the minimum in the d band.

The diffusion data can also be explained on this basis. As has been pointed out, the diffusion of a lenticular or toroidal ion is difficult, involving large movements of the matrix atoms. However, during movement of the atom the remaining degeneracy will be removed, and some of the levels will increase in energy. It is then possible for ionization of a lower level to occur, an electron being lost to the conduction band of the metal. (This electron will remain in the general vicinity of the interstitial because of the distortion of the bands locally due to the excess charge on the ion.) This new ion will not only be smaller, but also its shape may change, thus making diffusion easier. If this ionization is the process for which activation is required in the diffusion, it follows that the activation energy for diffusion is unlikely to depend very strongly on the melting-point of the matrix and will certainly not approach zero as the melting-point falls to zero. If, however, the highest-filled level is deeply submerged below the Fermi surface, the ionization energy may exceed the activation energy for the normal lattice distortion mechanism, and consequently ΔH will show the normal dependence on the matrix melting-point. The condition for the appearance of a 'normal' activation energy is thus approximately the same as for the disappearance of appreciable solubility, explaining the difference in equations (3) and (4) for the small and large solubility interstitials.

It remains to determine the probable form of the oxygen ion in the systems with high solubility. On the basis of the previous argument the most likely forms would be those with one or two electrons short of a full shell, but in order to diffuse the ion with two electrons short would require only the energy difference between the filled level and the lower of the upper two levels. The major energy difference would be expected to be between the upper two levels, with the difference between the lower of these and the lower levels relatively small. During displacement, this gap would reduce still further,

and the ion would diffuse simply by changing its configuration and hence its shape. It seems more likely, therefore, that the oxygen is present as ions lacking only one electron from a full shell, that is, the O^- ion. Recent studies of the interaction energies between oxygen in solution and dislocations gives some support to the idea that a single negative charge should be assigned to the oxygen ion in high-solubility systems. Rosenfield and Owen[9] have shown that the yielding of tantalum containing small amounts of oxygen cannot be explained simply on the basis of elastic interaction, but that it is necessary to attribute a charge to the ion to interact with the dislocation dipole. Satisfactory agreement is obtained using a single negative charge for the oxygen ion.

NEW PROTON-CONTAINING OXIDES OF TITANIUM, ZIRCONIUM AND HAFNIUM

By F. K. McTAGGART

C.S.I.R.O. Division of Mineral Chemistry, Fishermen's Bend, Victoria, Australia

I HAVE reported[1] the reduction of ZrO_2 and HfO_2 using 'active' hydrogen produced in a discharge at 2,450 Mc/s, and gave an approximate value for the specific resistivity of the reduced ZrO_2. Since that time further experimental work has been done, and it now appears that these golden oxides, which exhibit metallic conductivity and have low resistivities, contain hydrogen and may be related to the various metal oxide 'bronzes'. The reactions do not occur with the neutral or excited hydrogen atoms produced by lower frequency discharges (50 c/s to 30 Mc/s) although many oxides are readily reduced under such conditions.

The high-frequency generator used was a Mullard fixed tuned (2,450 Mc/s) magnetron, 'Type *JN* 2/2·5*A*', capable of delivering about 2·5 kW of power at anode voltage and current of 4·8 kV and 750 m.amp respectively. The output of the magnetron was coupled by means of a length of air dielectric 70 ohms coaxial line to a short length of water-cooled wave-guide, constructed in a manner similar to that described by Shaw[2].

Power input to the magnetron was readily varied by adjusting the anode voltage by means of a variable auto-transformer fed from a constant-voltage 50 c/s a.c. source. Powers of 100 W–1·0 kW were used.

Materials utilized were: (*a*) TiO_2, ZrO_2 and HfO_2 powders prepared in a highly pure state in the laboratory, either by precipitation, or oxidation of 'iodide' metal turnings in oxygen; (*b*) compacts of these oxides made by pressing the powders at 10,000 lb./in.^{2} and sintering at 1,700° C; (*c*) pieces of ZrO_2 ceramic cut from 'Degussa' brand tubing; (*d*) titanium, zirconium and hafnium metal foil 0·005 in. thick, the latter containing approximately 1 per cent zirconium. Also tested in the apparatus were 'Specpure' ThO_2, CeO_2, Ta_2O_5, Nb_2O_5 and V_2O_5, and high purity aluminium and beryllium oxides in both powder and ceramic form. The hydrogen for the reductions was commercial cylinder gas containing approximately 0·5 per cent nitrogen.

Samples of oxides were placed centrally between the guide walls; powder in silica boats; compacts, ceramic pieces and metal in small supports made from 1/16-in. silica rod.

Pressures of hydrogen between 0·5 mm and 5 mm were used, but normally 2 mm was favoured since the discharge appeared to be most stable at this pressure, although the greatest yield of hydrogen atoms is achieved at about 0·5 mm (ref. 2.) After pumping the apparatus down to a few μ the hydrogen was fed into the working tube via a needle valve to the required pressure and the input to the magnetron was adjusted to about 100 W. If the discharge did not form, a high-frequency vacuum 'leak tester', held near the tube, proved an effective 'trigger'. The power input was then raised slowly to the desired level, which was, in the majority of experiments, about 500 W. Temperatures at the sample, which were measured by means of fine thermocouple wires, varied from 200° C to 1,200° C. depending on the power used, the latter value obtaining for input powers of the order of 1 kW.

The samples of metal foils were first coated with a layer of oxide by passing oxygen through the apparatus at about 1–2 mm pressure, and establishing a discharge with a power of 300–400 W. For treatment times ranging from a few minutes to 0·5 h, in the case of zirconium and hafnium, dense strongly adherent layers of oxide usually grey in colour were formed varying from a few tenthousandths of an inch to 0·0015 in. in thickness. Once the requisite oxide had been formed, hydrogen was substituted for the oxygen, resulting in a thin layer of 'golden oxide' on the previously formed oxide layer. Fig. 1 shows two cross-sectional views of metal-oxide–golden oxide layers, one a taper section, the other at right angles to the plane of the foil. The maximum thickness attainable was about 0·0003 in. For titanium the procedure was similar; but if oxidation was continued for a longer period the surface of the oxide layer became friable, and after hydrogen treatment the golden material could be scraped off quite readily.

In order to obtain the golden zirconium compound in a fully converted state, thin layers of ZrO_2 were deposited on silica plates from an aqueous suspension of finely ground oxide. These were then treated in the apparatus. There was no sign of reaction when the oxides of thorium, beryllium and aluminium were used, even when powers of 1 kW were used. CeO_2 reduced to the mustard-

Fig. 1. Showing from left to right Zr metal, ZrO_2, and 'golden ZrO_2' layers. *a*, × *c.* 75 and at an angle of a few degrees from plane of foil; *b*, × *c.* 560 at right angles to the plane of the foil

coloured CeO_3 : Ta_2O_5, Nb_2O_5 and V_2O_5 to black, electrically conducting lower oxides of metallic appearance, without exhibiting any golden colour.

The oxides of titanium, zirconium and hafnium, either as powders, compacts, ceramic bodies or layers on metal substrates were all readily converted on their surfaces to the golden materials. During hydrogen treatment metals underlying the oxide layers became brittle due to the uptake of hydrogen and some nitrogen (weak lines of ZrN were observed in X-ray examinations of the metal layers in samples of zirconium) and required careful handling. However, there is no evidence to suggest that nitrogen plays any part in the formation of the golden materials, and they certainly do not contain nitride.

It has already been noted that hydrogen atoms produced at relatively low frequencies have no effect on ZrO_2 or HfO_2 although they cause a marked greying of TiO_2. In the 2,450-Mc/s discharge there is a noticeable preferential reaction on surfaces which are at right angles to the direction of the electrostatic field within the guide, although the attack, is not necessarily confined to these surfaces. Reaction also occurs on such surfaces even when the spacing between them is of the order 0·001 in.

The extent of the reaction with time may be measured by noting the change of resistance across a surface. In Fig. 2 typical resistance values shown as ohms across a given surface of a ceramic body are plotted against time. Slight treatment resulted in a grey or black coloration; but the golden form quickly became apparent. Golden layers were produced equally satisfactorily by using lower power (about 100 W) for a longer period or higher power for a shorter period, and temperature did not appear to be an important factor—no differences in the final products could be detected. When zirconium oxide ceramics containing 3–5 per cent CaO as a stabilizer were treated much longer times were necessary for the formation of the layer, but the final result was the same.

Analysis of the materials established the fact that they contain appreciable amounts of hydrogen, the formula of the titanium compound being $H_{0\cdot2}Ti_{1\cdot00}O_{1\cdot3}$ and that of the zirconium $H_{0\cdot2}Zr_{1\cdot00}O_{1\cdot66}$. This indicated that reduction had occurred and that hydrogen was incorporated. The titanium compound was shown by X-ray analysis to be the TiO phase which is stated[3] to exist in the compositional range $TiO_{0\cdot7}$–$TiO_{1\cdot25}$. The specific resistivity, from measurements done on compressed powder was found to be approximately 0·004 ohm cm, and the conductivity was metallic in character, the resistance increasing slightly as the temperature was raised.

The golden zirconium compound has a structure which appears to be essentially that of ZrO_2, but the presence of several additional lines suggests a distortion of the lattice that could be due to the incorporation of hydrogen atoms. It has a specific resistivity of approximately 0·002 ohm cm, metallic conductivity, and at a hot junction between zirconium metal and the golden oxide electron flow is from the former to the latter. The thermo E.M.F. under these conditions is approximately 0·1 μV/deg. C.

All the golden oxides rapidly re-oxidize to white oxides when heated in air or oxygen, and in most chemical properties bear a close resemblance to the dioxides. They are quite stable under normal conditions.

Hydrogen atoms are not energetic enough to reduce ZrO_2 and HfO_2, although they reduce TiO_2. Hence a species having a higher energy than that possessed by a hydrogen atom must be responsible. The preferential reduction which occurs on surfaces at right angles to the electrostatic field suggests charged particles that are orientated to some degree in the field, possibly even accelerated to some extent in it. The most likely species appears to be the H_2^+ ion since it is unlikely that protons would be produced under the conditions obtaining in the wave-guide. It is interesting to examine the thermodynamic relationships of the oxides to hydrogen atoms and H_2^+ ions. We have the following equations to consider[4]:

$$\underset{-204}{TiO_2} + \underset{200}{4H} - Ti + 2H_2 + O_2 \quad \text{Additional energy required} + 4 \text{ kcal} \qquad (1)$$

$$\underset{2X-204}{2TiO_2} + \underset{100}{2H} - \underset{-340}{Ti_2O_3} + H_2 + O_2 \quad ,, \quad ,, \quad ,, \quad -32 \text{ kcal} \qquad (2)$$

$$\underset{-238}{ZrO_2} + \underset{200}{4H} - Zr + 2H_2 + O_2 \quad ,, \quad ,, \quad ,, \quad +38 \text{ kcal} \qquad (3)$$

$$\underset{-238}{ZrO_2} + \underset{714}{2H_2^+} - Zr + 2H_2 + O_2 \quad ,, \quad ,, \quad ,, \quad -476 \text{ kcal} \qquad (4)$$

In atomic hydrogen reactions such as these, water is not a final product, the gaseous products of reduction

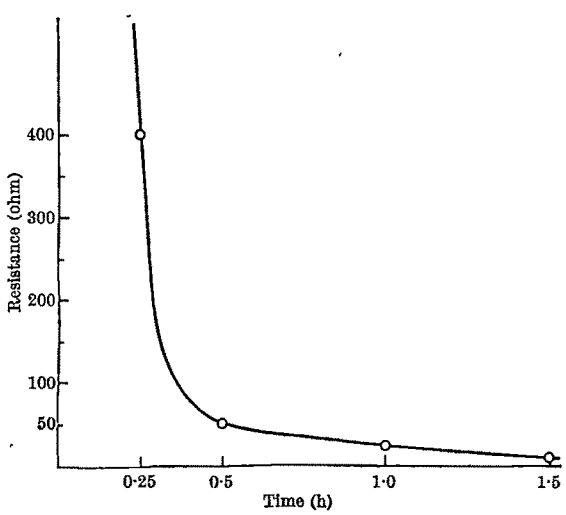

Fig. 2

being hydrogen and oxygen. Equation (1) indicates no reduction of TiO_2. However, reduction is known to occur, but probably not beyond the composition represented by Ti_2O_3. Substituting this compound for titanium metal we have equation (2), which agrees well with observation. For ZrO_2, equation (3) indicates no reduction, which is in fact what is observed. There is no evidence so far to suggest that there are any phases in the Zr—O system analogous to Ti_2O_3, Ti_3O_5, etc., so that equation (3) is probably valid. Equation (4) shows that for H_2^+ ions reduction should readily occur. This is again in agreement with observations. However, the H_2^+ ion carries sufficient energy, according to thermodynamic data, to reduce ZrO_2 to the metal, and also ThO_2, BeO, Al_2O_3, etc., yet these last-named oxides show no sign of being affected. A possible explanation is that at a composition MO_{2-x}, where x may be very small, these oxides exhibit greatly increased stability.

The phases in the Ti—O system have been thoroughly investigated and are now well established. In the present work it would appear that reduction so far as the monoxide phase occurs and that hydrogen enters this lattice as protons, giving rise to electrons which confer a high conductivity in the material.

Simonenko[5] stated that ZrO_2 was reduced in a d.c. arc between tungsten electrodes, in an atmosphere of hydrogen, and that this was due to the effect of ions of molecular and atomic hydrogen. It is not clear to what extent the ZrO_2 was reduced, although the impression is obtained that the claim is for reduction to the metal. If this is so it must be regarded as doubtful, since many other workers have failed to obtain metal even under extreme conditions. Norton and Kingery[6] and Kramers and Smith[7] have shown that the black material obtained when ZrO_2 is fired in vacuum at 2,200° C is a solid-solution of zirconium in ZrO_2, which may contain as much as 15 mole per cent zirconium. X-ray patterns of the solid solutions all conform to ZrO_2. Specimens of these black materials prepared in our laboratory were not electrically conducting. It is probable, however, that the golden zirconium (and hafnium) compounds are analogous to them in so far as the zirconium : oxygen ratio is concerned, but that, as in the case of the titanium compounds, the incorporation of hydrogen into the lattice has the effect of producing electrons, which are available for conduction as in metals. The question of the relationship of these golden compounds with the tungsten oxide and other 'bronzes' (for example, ref. 8) arises. It may well be that these hydrogen-containing, electrically conducting oxides, and in particular those of zirconium and hafnium, are bronzes in which hydrogen atoms replace the usual alkali metal atoms. Electron diffraction investigations at present being carried out should resolve this, and it is hoped to present detailed structures in the near future.

TEMPERATURE OF SHOCKED ARGON AND METHANE

By C. E. REYNOLDS and L. B. SEELY

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

RECENTLY an experiment was reported[1] which, it was claimed, showed that the light emitted from within a granular pressing when strongly shocked did not, for the most part, arise from the compression of the interstitial gas. Evidence on this point was obtained by repeating an experiment of Paterson[2] on granular sodium chloride shocked by high explosives. Light emitted by a pressing when the interstitial gas was methane was compared with light emitted when the gas was air. It could easily be estimated, and in fact was demonstrated experimentally, that free-running shocks from high explosives in these two gases have very different brightnesses. Failure to note much difference in brightness between pressings filled with methane and pressings filled with air was cited as evidence that the gases were not responsible for the major part of the very intense light observed.

It may be objected that much higher local pressures exist in pressings than in free-running shocks and that the difference in temperature between these two gases would therefore be expected to disappear in the case of the pressings. Such higher pressures could indeed exist in small interaction regions even though it has been observed that the overall velocity of the shocks through the pressings was lower than through the open gas chambers. Assuming that the conditions in the pressings are in fact severe, we propose to demonstrate that the temperature differential between two such gases as methane and air will remain.

We have performed calculations of the temperatures to be expected for various shock pressures in methane and in argon. These calculations are of interest not only because of the foregoing specific experiment but also as illustrations typical of the behaviour of ionizing and dissociating gases. Argon was not used in the experiment, but perhaps should be in future experiments, since it is a good example of a monatomic low-heat-capacity gas which can be expected to reach very high shock temperatures. Methane provides perhaps the best example, from the point of view of both experiment and calculation, of the effects of high heat capacity and dissociation in producing relatively low shock temperatures. Most gases which can be conveniently used in experiments lie between these two extreme examples.

The initial conditions for the calculations were one atmosphere and 300° K. The usual hydrodynamic equations and the equilibrium relations among the various possible species were solved simultaneously on an IBM 704 computer, using a programme written by R. E. Duff and Wildon Fickett[3]. For argon the species considered were Ar, Ar^+, and e^-. For methane the species were CH_4, C, H_2, H, H^+, C^+, and e^-; in a few calculations several other possible hydrocarbon-fragment species[4] were allowed in the equilibrium with only minor alterations in the results. The individual species were assumed to obey the perfect gas law; but the behaviour expected of perfect gases, such as a density-ratio limit of four for argon, was not in evidence. This was the result of the nature of the enthalpy and free-energy functions used, which included the contributions of internal degrees of freedom with the proper temperature dependence. Allowance was made for the increasing number of states at high energies, for stretching, and anharmonicity where appropriate. The functions used have been given in tables elsewhere[4–7].

The ratio of shock temperature T to initial temperature T_0 for the two gases is plotted in Fig. 1 for a

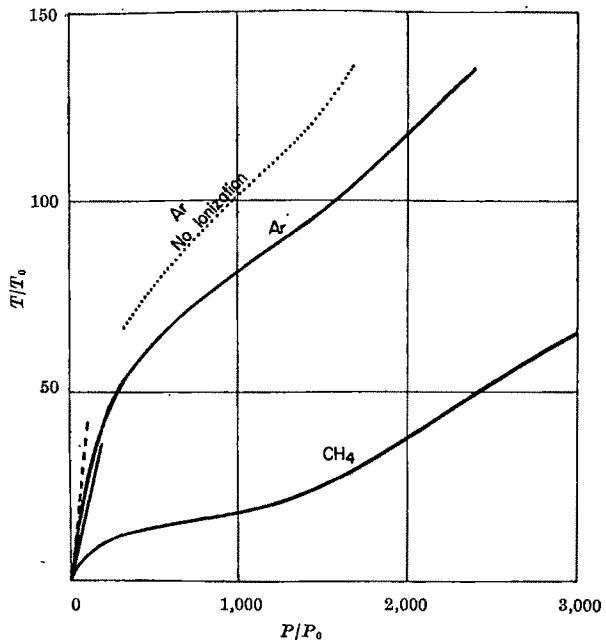

Fig. 1. Temperature ratios across shock fronts in argon and methane as a function of the pressure ratios. Subscript zeros refer to unshocked conditions (P_0 = 1 atm, T_0 = 300° K). The dashed line shows the temperature ratios in argon if the gas were considered to be a perfect gas with constant heat capacity $C_P = 5/2R$. The solid straight line shows the corresponding perfect-gas, no-reaction temperature ratios for methane with a constant value of the heat capacity appropriate to 300° K (with the internal degrees of freedom included). The dotted line indicates the case for argon in which the heat capacity has been allowed to increase as the higher excited states become important, but no ionization is permitted

range of shock pressures. The dashed and solid short segments in Fig. 1 show the temperature which would exist in argon and methane respectively if the gases were considered to be perfect, non-reactive, and to have constant heat capacities. Under these assumptions the heating in both gases is extreme, and the temperatures at a given pressure ratio are approximately proportional to the specific heats.

In contrast to the constant heat-capacity assumption, the more realistic calculations show that the argon temperature is soon restricted by increase of the heat capacity due to excitation and ionization. The temperature calculated when no ionization is allowed but the heat capacity is considered to increase due to excited states is shown by the dotted line in Fig. 1. The degree of ionization in argon for various pressure ratios across incident and reflected shock fronts is shown in Fig. 2, where it may be seen that ionization starts at low pressures and continues throughout the range of shock strengths calculated.

For methane, a similar restriction of the temperature (Fig. 1) results from dissociation and the increase in the heat capacity. In Fig. 3, it will be noted that dissociation occurs at relatively low shock pressures. Consequently, the temperature in this material remains relatively low until quite high pressure ratios are reached. Ionization is appreciable only for pressure ratios above 2,500.

The relation of these calculations to the measurements that have been made can be seen in Fig. 4, where the shock velocity has been plotted against the shock pressure ratio. On this plot the measured velocities of the free-running shocks in argon and methane (measured from the film reproduced in ref. 1) induced by explosion of Comp. *B*-3 are shown by circles on the appropriate curve, and the measured velocity of a shock driven by Comp. *B*-3 through granular sodium chloride at pour density is indicated by a dashed line. This last velocity is practically the same whether argon or methane is used as the interstitial gas. For matching at interfaces between these gases and other materials, the pressure versus particle-velocity plot included in Fig. 4 will be useful.

High-pressure regions, if present, must occur as a result of multiple reflexions within the interstices of a granular pressing. As an indication of how such repeated reflexions might affect the state of argon and methane, Figs. 2, 5, 6 and 7 present a comparison of the conditions reached in the initial shock and in a reflexion against an incompressible wall. No more than one reflexion can be calculated with the present programme. It will be noted that for a given pressure ratio the temperature is always lower if achieved by reflexion than if achieved by one (stronger) shock. The relation between a typical incident

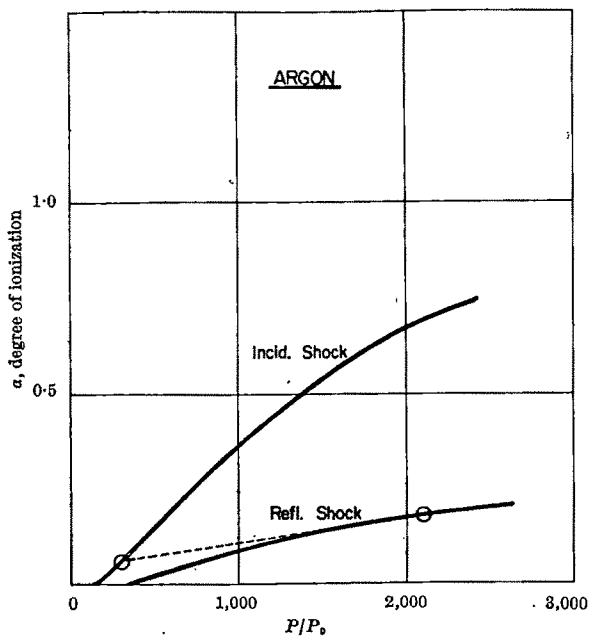

Fig. 2. The degree of ionization α, the number of electrons divided by the initial number of argon atoms, as a function of the pressure ratio. The upper curve is for incident shocks, and the lower curve is for the reflexion of those shocks against a rigid wall. The two circles represent a typical associated pair of incident and reflected shocks

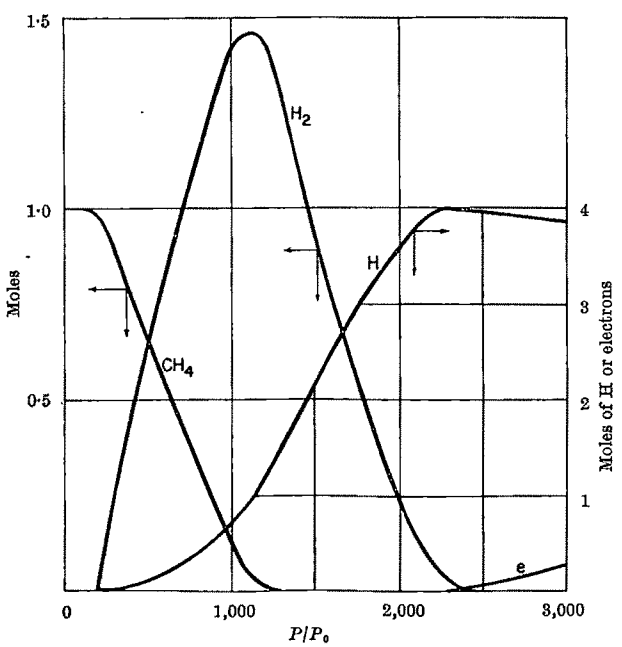

Fig. 3. The amounts of some of the species in shocked methane as functions of the pressure ratio across the incident shock front. The curve marked *e* is the number of moles of electrons; this would reach the number five on the scale at the right when each atom in the gas had lost one electron

shock and its reflexion is shown in Figs. 2, 5, 6 and 7 by the circles on the incident and reflected shock curves.

Attention is directed to the Hugoniot for the incident shock in Fig. 7, which shows that for a pressure ratio of about 500 the density ratio is about 20, whereas for a stronger shock with a pressure ratio of about 2,500 the density ratio is approximately ten. However, on reflexion of even a fairly weak shock a very high density is achieved. This is an example of the complicated effects caused by processes that absorb energy and change

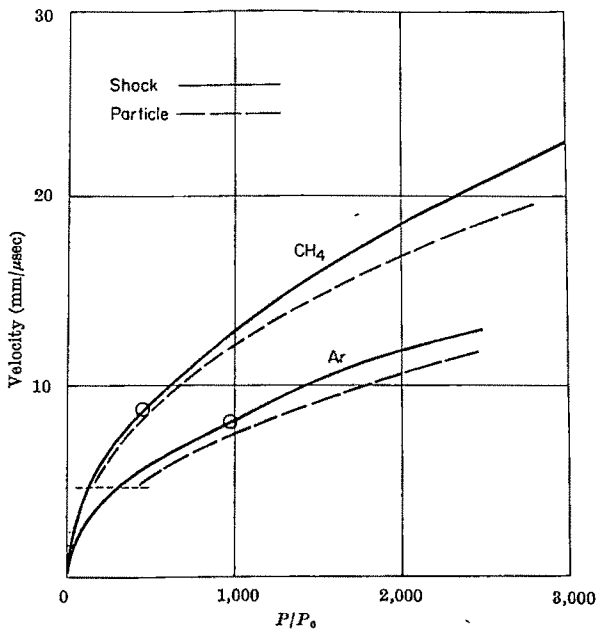

Fig. 4. Shock and particle velocities in argon and methane for various pressure ratios across the fronts. The circles show the velocities of a free-running shock from Comp. *B*-3 in methane and argon, the former measured on the film published by Blackburn and Seely (ref. 1), and the latter specially measured by Gardner. The dashed line represents the velocity caused by Comp. *B*-3 in a sodium chloride pressing. This has about the same value when either gas fills the interstices

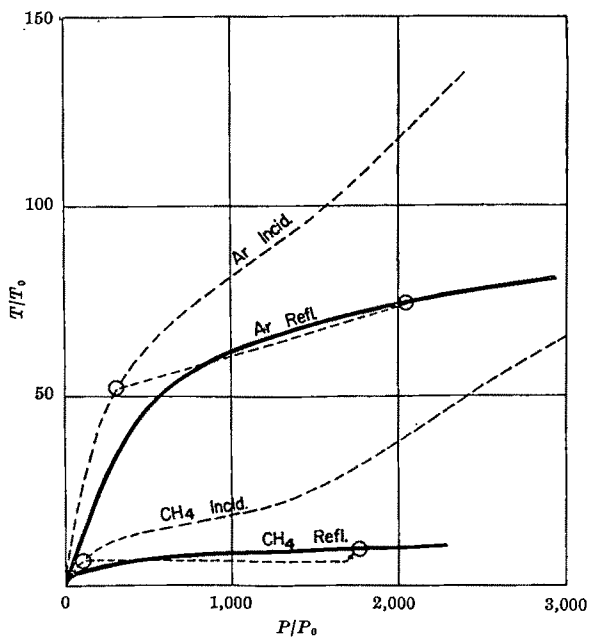

Fig. 5. Comparison of temperature ratios in incident shocks with ratios achieved by a single perfect reflexion for argon and methane. The circles on the incident curves represent values for free-running shocks in the low strength range (4·7 mm/μsec). The circles on the reflected curves indicate the perfect reflexions associated with those initial shocks

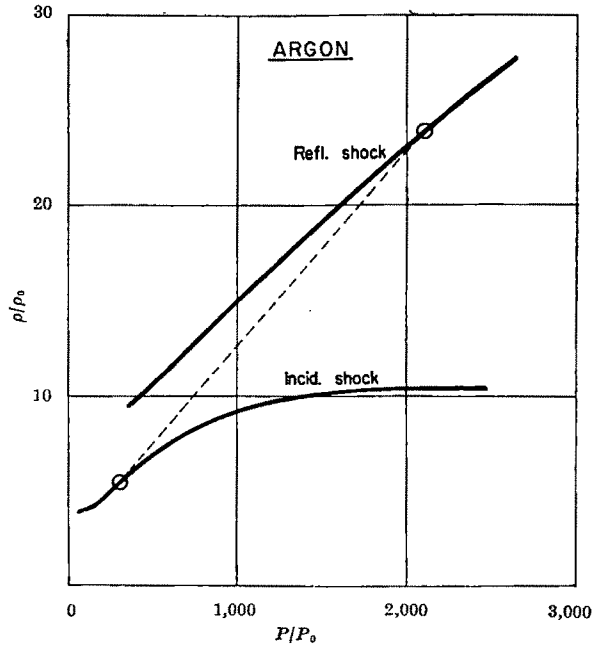

Fig. 6. Comparison of the density ratios of argon in incident shocks with the corresponding density ratios in reflected shocks

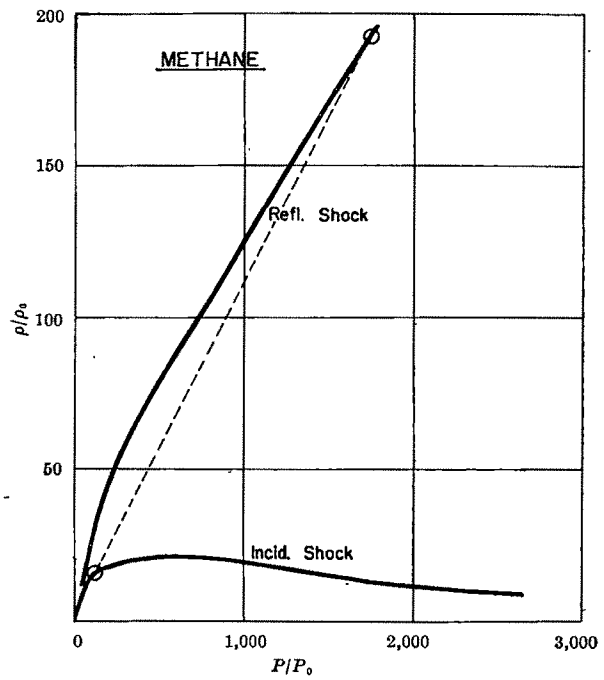

Fig. 7. Comparison of the density ratios of methane in incident shocks with the corresponding density ratios in reflected shocks

the number of particles in a shock. Hydrodynamic treatments which ignore such processes can yield very misleading results. Additional corrections to the present calculations, such as the use of a real-gas equation of state, would be expected to produce relatively minor changes in the results.

These calculations demonstrate that for shock strengths that are nearly the same in argon and methane the shocked argon is always much hotter. At the most severe conditions in the calculations all indications are that this situation will continue to even stronger shocks. The temperature differential is maintained in the first reflexion.

We thank Garry L. Schott for his help in setting up these calculations and Robert L. Mowrer for preparing the

graphs. We thank S. D. Gardner for the measurement of the shock velocity in argon from Comp. *B*-3. This work was carried out under the auspices of the U.S. Atomic Energy Commission.

LIMITATIONS OF ELECTRONIC INTERPRETATIONS OF CHEMICAL PHENOMENA

By Dr. C. R. ALLEN and Dr. P. G. WRIGHT
Chemistry Department, Queen's College (University of St. Andrews), Dundee

At the present time many widely used chemical texts seek to interpret numerous phenomena in terms of what are known as electronic theories. These views emphasize the transfer (or 'displacement', as in the 'inductive effects' of certain works on organic chemistry) of electrons, and sometimes succeed on such a basis in correlating a range of chemical properties. It seems timely, however, to examine carefully and critically certain serious limitations of such theories.

Much of the present article is concerned with the more plausible of these views, but some preliminary remarks deal with what is probably the crudest (and, fortunately, least credited) of the electronic theories—that which seeks to reduce all chemistry to a ruling tendency of atoms to attain an inert-gas electronic structure. A quantitative examination of the demerits of such a view is indeed instructive. Consider, for example, the formation of sodium chloride from its elements. The sodium atom does not readily lose an electron, as is clear from the large quantity of energy * (the ionization energy) required to bring about such a loss:

$$Na(g) \rightarrow Na^+(g) + e^-(g) \qquad \Delta H^\circ = + 120{\cdot}0 \text{ kcal mole}^{-1}$$

By the relevant thermochemical criterion, the dissociation of hydrogen to atoms is a process which occurs more readily :

$$H_2(g) \rightarrow 2H(g) \qquad \Delta H^\circ = + 104{\cdot}2 \text{ kcal mole}^{-1}$$

Nor does the positive electron affinity (Table 1) of chlorine make electron transfer energetically favoured:

$$Na(g) + Cl(g) \rightarrow Na^+(g) + Cl^-(g) \quad \Delta H^\circ = + 35 \text{ kcal mole}^{-1}$$

and for this process equilibrium lies far over to the left. At 1,000° K the equilibrium constant (equal to 0·110 $e^{-\Delta H^\circ/RT}$, where the factor 0·110 allows for the statistical weights of the species concerned) comes at the most to 7×10^{-9}. At equilibrium in a gas of atoms, only a fraction slightly less than 10^{-4} would be present as ions. In the formation of sodium chloride from its elements, the process actually concerned is (stoichiometrically) :

$$Na(s) + \tfrac{1}{2}Cl_2(g) \rightarrow NaCl(s)$$

and it must be pointed out that the only exothermic step in the similar sequence to which this may be reduced is that involving the lattice energy :

$$Na^+(g) + Cl^-(g) \rightarrow NaCl(s)$$

which has no connexion with inert-gas structures as such.

Properties of the halogens. An approximate generalization exists to the effect that among comparable atomic species the smaller (1) are more strongly bound in molecules (2) more readily acquire an extra electron. The properties of the halogens (Table 1) show that this rule has some force, but that there are unquestionably exceptions to it. The dissociation energy, D(F–F), of molecular fluorine and also the electron affinity of that element are smaller than the corresponding quantities for chlorine, in contrast both to this rule and to trends among the heavier of the halogens.

* Thermochemical data are here given, unless specified otherwise, as standard changes of enthalpy at 25° C.

Table 1. Properties of the Halogens

All quantities are given as ΔH° (kcal mole^{-1}) at 25° C

Data from Cottrell (ref. 1), Pauling (ref. 2) and Berry *et al.* (ref. 2*a*)

It is interesting to note that there is evidence[3] that the (first) electron affinity of oxygen is less than that of sulphur.

Standard electrode potentials. A quantitative discussion of equilibria involving ions in solution may be based on measurements of standard electrode potentials, that is, of the E.M.F. of a reversible cell one of the electrodes of which consists of a metal M dipping into a solution of its ions at unit activity, and the other consists of hydrogen at unit pressure passing over an inert (platinum) rod dipping into a solution of hydrogen ion at unit activity. The chemical reaction occurring in such a cell is:

$$\frac{z}{2}H_2(g) + M^{z+}(aq) \rightarrow zH^+(aq) + M(s)$$

and the associated standard change of free energy ΔG° and standard electrode potential E° are related by the equation:

$$\Delta G^\circ = - zFE^\circ$$

(where F is the Faraday). Thus the standard electrode potential is directly proportional to the standard change of free energy for the reverse of the reaction written.

The (reverse) reaction may be expressed in terms of a sequence of four processes, of which the first three depend on the identity of the metal concerned.

(1) $M(s) \rightarrow M(g)$ sublimation

(2) $M(g) \rightarrow M^{z+}(g) + ze^-(g)$ ionization

(3) $M^{z+}(g) + zH^+(aq) \rightarrow M^{z+}(aq) + zH^+(g)$ 'solvation'

(4) $zH^+(g) + ze^-(g) \rightarrow \frac{z}{2}H_2(g)$

Changes of enthalpy and free energy for the whole process may be obtained by summing those for these four steps, and contributions to the standard electrode potential thus deduced. Of the three which depend on the metal, only step (2), ionization, involves the transfer of electrons, and, in general, contributions from both sublimation and solvation may be important.

The electrochemical data required for examining these points can be obtained from a compilation by Parsons[4], while the latent heats of sublimation have been taken from Cottrell[1]. It is evident (Fig. 1) that the standard electrode potential is not closely correlated with the contribution to it arising from ionization. Further (Fig. 2), there is no close correlation with the first ionization potential. There is only one even moderately successful correlation

Table 2. An Analysis of Data relating to Standard Electrode Potentials

		Be	Zn	Cu	δ(Cu–Be)	δ_v(Cu–Be)	δ(Cu–Zn)	δ_v(Cu–Zn)

with a definite quantity relating to a propensity to transfer electrons, the correlation[5] with the (thermionic or photoelectric) work function (Fig. 3). Even this relation is obviously of limited validity.

A detailed examination of certain pairs of metals (Table 2) confirms that any or all of processes (1)–(3), sublimation, ionization, or solvation, may be decisive for the observed differences of standard electrode potentials*. The difference between copper and beryllium is

* For each process, values of ΔG° should properly be compared rather than values of ΔH°. However, the terms due to changes in entropy are relatively small (for example, about 8 kcal mole^{-1} for sublimation), and do not vary greatly between one metal and another.

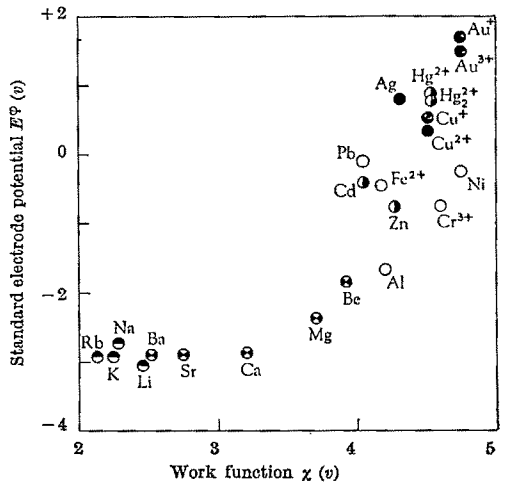

Fig. 3. Comparison of standard electrode potentials with work functions. (Values of the work function are from Rivière (ref. 6) and Landolt-Börnstein (ref. 7))

clearly due almost entirely to differences in the thermochemistry of solvation, while the difference between copper and zinc is mainly due to the large difference in their latent heats. The greatest contribution to the difference between lithium and silver comes from the difference in ionization potentials, but both other factors contribute (solvation making the smallest contribution).

In conclusion, the evidence shows clearly that standard electrode potentials do not reflect very closely any relative propensity of atoms to lose electrons.

Ionization of organic acids. Relative strengths of such acids as chloroacetic and acetic have been correlated with some success on the basis of an assumed 'inductive effect':

$$Cl \longleftarrow CH_2 \longleftarrow CO \longleftarrow O \longleftarrow H$$

reducing the chance of finding an electron between the final O and H, and thus weakening the binding of the proton to the remainder of the molecule. The ionization constants of such acids differ markedly, but among some groups of acids (Table 3) the strengths differ relatively little, and no interpretation in terms of 'inductive effects' is possible.

As is clear from the data[8,9] presented in Table 3, no regular change in acid strength results from substitution of either (1) n-alkyl groups of increasing length; or (2) successive methyl groups, for the α hydrogen atoms of acetic acid. The really significant point[10] about these acids is that their ionization constants at a given temperature are nearly the same.

Certain pairs of acids reverse their relative strength as the temperature changes. Thus, if differences between acetic acid and 2-ethyl butanoic acid were really a consequence of 'inductive effects', the inductive effect of the two ethyl groups would have to be in opposite senses above and below 29° C. Again, relative strengths of acids

Table 3. Data for the Ionization of Substituted Acetic Acids (in Aqueous Solution)

Values of pK_a at 25° C:

1/2 Penta-1,3-diene	−27·05
1/2 Penta-1,4-diene	−30·4
1/2 *Cyclo*pentadiene	−25·4
1/2 *Cyclo*hexa-1,3-diene	−27·7
1/2 *Cyclo*hepta-1,3-diene	−25·65

are sometimes reversed by change of solvent: in aqueous solution *o*-nitrobenzoic acid (pK_a 2·21) is stronger than 3,5-dinitrobenzoic acid (pK_a 2·80), but in ethanolic solution the reverse is the case[11] (respective pK_a's 8·62 and 8·09). Here, too, factors outside the molecule have to be taken into account.

One further important point brought out by the results[8] is that differences in strengths of acids in aqueous solution are in the majority of cases due largely or entirely to differences not in heats of ionization but in entropies of ionization.

Thermochemistry of the hydrogenation of the alkenes. Since accurate and reliable data[12] have been available for the heats of hydrogenation of numerous alkenes, various attempts have been made to explain the variations (Table 4) among the various substances. For example, buta-1,3-diene has often been compared with but-1-ene, and 'resonance energies' deduced. Over-enthusiastic interpreters seem, however, in general to have overlooked the fact that the heat of hydrogenation changes more between but-1-ene and *trans* but-2-ene than between but-1-ene and buta-1,3-diene. There are very considerable variations among compounds which are written with one isolated double bond (ethylene and *cyclo*-octene being the two extremes); and the variations between dienes classed as conjugated and those classed as not conjugated are smaller. In short, comparison with simple alkenes provides no thermochemical evidence for conjugation in dienes, and any discussions of such matters must rest on, for example, data for internuclear distances (cf. Pauling[2]).

We thank Dr. J. L. Copp, Dr. R. Foster, Dr. R. F. Jameson and Dr. E. T. Stewart for valuable discussions on a number of points related to this work.

GEOLOGY AND GEOCHRONOLOGY OF THE SEYCHELLES ISLANDS AND STRUCTURE OF THE FLOOR OF THE ARABIAN SEA

By B. H. BAKER
Geological Survey of Kenya, Nairobi
AND
Dr. J. A. MILLER
Department of Geodesy and Geophysics, University of Cambridge

THE Seychelles Archipelago in the western Indian Ocean consists of a large number of islands, most of which are coral atolls and sand cays of relatively recent construction. The Mahé-Praslin group of islands, the principal islands of the archipelago, are situated approximately 1,000 miles east of Mombasa, and have been known for some time to be composed largely of granite[1,2]. Recently, however, a comprehensive geological survey of the Seychelles has been made by one of us (B. H. B.)[3], and a number of age determinations of Seychelles rocks have been made by Miller and Mudie[4]. Furthermore, geophysical work is in progress in the Seychelles area as a part of the oceanographic research of the International Indian Ocean Expedition[5]. The Mahé-Praslin group consists of 24 inhabited islands totalling some 75 square miles in area, which rise from the central part of the Seychelles Bank, a submarine bank generally at less than 200 ft. below sea-level, which covers approximately 16,000 square miles, and is the northern extremity of the Mascarene Bank linking the Seychelles, Reunion and Mauritius.

The dominant rock type in the Mahé-Praslin group of islands, excepting Silhouette, is Precambrian hornblende granite which shows very little variation, and which is evidently the core region of a granite batholith. Although Bauer[2] reported blocks of hornfelsic sediments on Silhouette and Ile aux Cerf, these occurrences have not been found during subsequent surveys. No wall rocks are therefore exposed, and the margins of the batholith lie somewhere on the Seychelles Bank beyond the islands.

The Mahé granite is characterized by ubiquitous microperthitic feldspar and a deep green hastingsite amphibole. Some varieties of the granite in Praslin contain biotite in place of hornblende, and local variations in composition range between alaskite and granodiorite. In western Mahé and on some of the eastern islands of the group, granite porphyry and porphyritic granite are developed

$\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr.$^{-1}$ $\lambda_e = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$

as a gradational facies of the main body. Aplites and small quartz veins are present, though pegmatites are absent. Certain zones of the Mahé granite, at the north-western coasts of the island, contain numerous flow-aligned xenoliths of dioritic and gabbroic composition, and larger partly assimilated rafts of hybrid intermediate plutonic rocks.

The granites display no structural features apart from jointing—they are anorogenic in character. Small shears trending north-east show evidence of slight dextral displacements.

Dolerite and basalt dykes are numerous on all the granitic islands, and occur as north-westerly trending swarms in the granite joint system. Two main varieties of dykes are distinguishable, porphyritic metadolerites and epidiorites of Precambrian age, and olivine alkali-dolerites probably of Tertiary age. The metadolerites are all affected by hydro-thermal alteration to some extent, with the formation of chlorite, the conversion of pyroxene to uralite, and, in extreme cases, saussuritization with the production of uralite, epidote and the breakdown of calcic plagioclase to sodic varieties and quartz. The olivine dolerites, on the other hand, are fresh or only slightly altered, and in most specimens an analcite mesostasis can be detected, indicating an alkaline tendency.

Silhouette Island and its neighbour, Ile du Nord, situated on the western side of the granitic islands, are composed of Tertiary syenite, diorite and microgranite. The greater part of Silhouette is composed of syenite, locally olivine-bearing, enclosing a microgranite stock. The occurrence of annular zones of microsyenite on the eastern side of the Island confirm that the intrusive is in the form of a syenite–microgranite ring complex of a kind common in Africa.

Age measurements were made on the samples listed here using the isotope dilution technique of potassium–argon dating. Potassium oxide contents were measured using a flame photometer, and argon-40 volumes estimated from the isotopic ratios of the argon released by fusion of the rock sample plus a known volume of enriched argon-38 added as internal standard.

Specimens *BT*.1*a*, *BS*.3*a*, *BS*.4 and *BW*.1 were measured using chippings of the whole rock as described by Miller and Mussett[6], whereas the remaining samples were measured on separated minerals. Results are shown in Table 1.

A previous measurement made on a sample of biotite from Mahé granite[4] yielded an age of 654 ± 17 million years. Wasserburg *et al.*[7] have since confirmed this figure by applying the rubidium–strontium method (638 ± 25 and 687 ± 34 million years). The average of the three samples of hornblende (*S*/26, *S*/101, *S*/147) from Mahé granite is somewhat lower (554 million years), due perhaps to slight alteration.

Hornblende from Central Praslin (*S*/75, 647 ± 55 million years) is in good agreement with the potassium–argon determination on Mahé biotite and the rubidium–strontium measurements of Wasserburg *et al.* It is concluded that the true age of the Mahé Island granite is about 650 million years.

Samples of basic rocks from Mahé are somewhat altered, thus the apparent ages they yield can only be taken as minimum values. The close agreement of sample *BT*.1*a* (645 ± 55 million years) with the age of the granite would suggest that they are closely associated genetically, and date from the late Precambrian.

The ages of the Silhouette syenite, though they show variations, average at 46 million years and indicate a late Eocene age for this ring complex. These variations are thought to have arisen from unrepresentative sampling of the altered pyroxene. Measurements on the olivine–alkali basalt dyke from Praslin (averaging at 50 million years) suggest that this phase of dyke injection was associated with the syenite–microgranite complex of Silhouette. This conclusion is supported by the common association of olivine alkali basalts and olivine syenites in other alkaline complexes.

The samples that have been dated are listed here, with localities and mention of the salient petrographic features:

S/26. Hornblende granite: 400 yards north-west of Anse Etoile, north-east Mahé. Patch-perthite and oligoclase feldspar, aggregates of fine deep green hornblende, iron oxide grains, sphene.

S/101. Hornblende alaskite: north-west summit of Trois Frères, Central Mahé. Perthite feldspar, ragged hornblende partially chloritized. Slight limonitic alteration.

S/147. Hornblende granite: south-east end of Anse Bazacar, near Pte. Police, south Mahé. Perthite feldspar, small deep blue-green riebeckite grains, some epidote and magnetite.

S/75. Hornblende granite: Nouvelle Decouverte survey beacon, Central Praslin. Turbid patch-perthite, minor oligoclase, sub-hedral blue-green hornblende.

BT.1*a*. Basalt dyke: west end of Bel Ombre bay, north-west Mahé. Prismatic plagioclase, augite mostly converted to uralite, iron oxide and brown chlorite. Pools of secondary calcite.

BS.3*a*. Epidiorite: 150 yards south of Sunset Café, north-west Mahé. Highly altered rock composed of hornblende, epidote, zoisite, chlorite and an oligoclase–quartz matrix.

BS.4. Metabasalt: 150 yards south of Sunset Café, north-west Mahé. A saussuritized basalt with chlorite in the matrix.

S/460. Porphyritic syenite: Roche Marceline, south-west Silhouette. Perthite feldspar, diopsidic pyroxene prisms altering to uralite–chlorite–magnetite aggregates with apatite.

BW.1. Olivine–dolerite: on Grand-Anse–Baie St. Anne road 100 yards south of the Vallee de Mai sign-post, Praslin. Almost unaltered olivine–augite dolerite. Partial chloritization of olivine and some carbonate in matrix.

Geochronology and Regional Geological Setting

The discovery that the Seychelles granites are of late Precambrian age renders their setting in an oceanic environment a unique geological phenomenon. The

Mahé–Praslin granite is almost certainly a single plutonic mass of anorogenic character, and must have been emplaced in a crust at least 1 mile thick. Seismic refraction work by Gaskell and Swallow[8] shows that granite underlies the coral on the Seychelles Bank and extends to a considerable depth. This crust is represented on the extensive Seychelles Bank, the central part of which is apparently composed of Precambrian granite[5], and is traversed by metadolerite dykes. The extent of this crust of continental type is unknown, but it is not unlikely that the adjacent Fortune and Saya de Malha Banks, which together with the Seychelles Bank form the northern extremity of the Mascarene Ridge, are composed of sedimentary or plutonic rocks. The islands of the southern part of the Mascarene Ridge—Reunion and Mauritius—are, however, relatively recent volcanoes. The Amirante Ridge to the west of the Mahé–Praslin group is covered by coral formations, but is topographically linked to the Seychelles Bank by a ridge some 5,000 ft. above the general level of the ocean floor, and may also be composed of sedimentary and igneous rocks, for it is in direct alignment with the major fault which bounds the eastern side of Madagascar.

It is therefore probable that the Seychelles area contains substantial expanses of continental formations which are partly or wholly of late Precambrian age. The ages obtained from the granites and metadolerites fall within the age-range of the Mozambique Belt of the eastern part of Africa and Madagascar[9]. This observation has led to renewal of the suggestion that the Seychelles may have originated during the fragmentation of Gondwanaland by continental drift[4,10]. The geology of the coastal region of East Africa and Mozambique contains evidence of intermittent down-flexuring of the Mozambique parageosyncline situated along the Mozambique Channel and in the Somali basin, from Karroo (late Carboniferous–Permian) to late Tertiary times[11]. It seems possible that the eastern part of the continent of Africa once extended as far as the line of the Mascarene Ridge, a hypothesis supported by the contrast between the form of the floor of the Arabian Sea and that of the remainder of the Indian Ocean[12]. The East African and Lebombo swells on one side and Madagascar and the Mascarene Ridge on the other may represent the marginal uplifts of this para-geosynclinal zone.

The occurrence of an early Tertiary syenite ring complex with associated alkali dolerite dykes strengthens the connexion with Africa, for similar complexes of about the same age are widespread from Kenya to Nyasaland. Such syenite complexes are typical of continental kratonic areas.

Present-day work by the geophysicists in R.R.S. *Discovery III* during the International Indian Ocean Expedition may be expected to throw much further light on the structure of the floor of the Arabian Sea. In particular, the hypothesis outlined here can be tested by gravity, magnetic and bathymetric traverses across the Mascarene and Carlsberg Ridges, and between the Seychelles and the East African coast. The nature and extent of the fracture on the eastern side of Madagascar and its northward continuation towards the Seychelles can also be investigated, together with the structure and composition of the crust in the Mozambique Channel and in the off-shore region of the East African coasts.

We thank Dr. G. J. Wasserburg *et al.* for informing us of their rubidium–strontium age determination on Mahé granite, prior to publication.

LAVA TUNNELS ON SUSWA MOUNTAIN, KENYA

By L. A. J. WILLIAMS
Mines and Geological Department, Nairobi

SUSWA mountain (Ol Doinyo Nyukie) is situated centrally in the eastern Rift Valley, some 30 miles west-north-west of Nairobi. It is composed entirely of Quaternary volcanic rocks, mainly trachytes, soda-trachytes and phonolites, together with a variety of pyroclastic material. The section of the Rift Valley including Suswa has yet to be mapped systematically by the Geological Survey of Kenya, but a great deal of information has already been obtained by several Government officers during visits to the area[1]. Suswa is essentially a well-preserved caldera, some seven miles across, in the centre of which is situated a remarkable circular moat more than 700 ft. deep, a quarter to one mile wide and three and a half miles in outside diameter. The inner wall of the moat is formed by a massive cylindrical block of lava two miles across. The highest point of the mountain (7,732 ft.) is on the south side of the moat and on the rim of a large truncated explosion vent, while the surrounding plains lie at altitudes of 5,000–5,500 ft.

Large cave-like or tunnel-like features, leading from deep depressions in the lava surface on the eastern flanks of Suswa, were first reported by Mr. D. Hobden—a Government prospector—during geothermal investigations in 1962. A field party led by Mr. Hobden briefly examined the tunnels later in the same year and, in January 1963, I was present during a further expedition to Suswa when the underground features were investigated in a little more detail. The success of this excursion was largely attributable to the work carried out by Mr. L. Wateridge of the Kenya Veterinary Department, ably assisted by a party from the Royal Staffordshire Regiment.

Recognition of the Suswa tunnels depends on fortuitous roof collapse to produce roughly circular holes or depressions in the lava surface. Aerial photographs show no deep clefts in the lava, such as would be expected from the total collapse of a tunnel roof. At present, holes are confined to an area of less than a square mile immediately outside the original wall of the caldera, the distribution suggesting that two main tunnels or networks diverge eastwards. The only known underground features occur in a series of lava flows which poured eastwards through a breach in the caldera wall. Individual flows, which are evidently 30–60 ft. thick, were extruded rapidly one upon the other and preliminary examination suggests that the dark glassy lava is of phonolitic or trachytic composition. The flows clearly post-date the main caldera subsidence but eruption occurred before formation of the moat, which truncates lavas overlying those bearing the tunnels. These overlying flows partly inundated the caldera floor and poured over the rim to the south and east.

The holes which provide access to the tunnels contain mounds of lava blocks and soil representing the remains

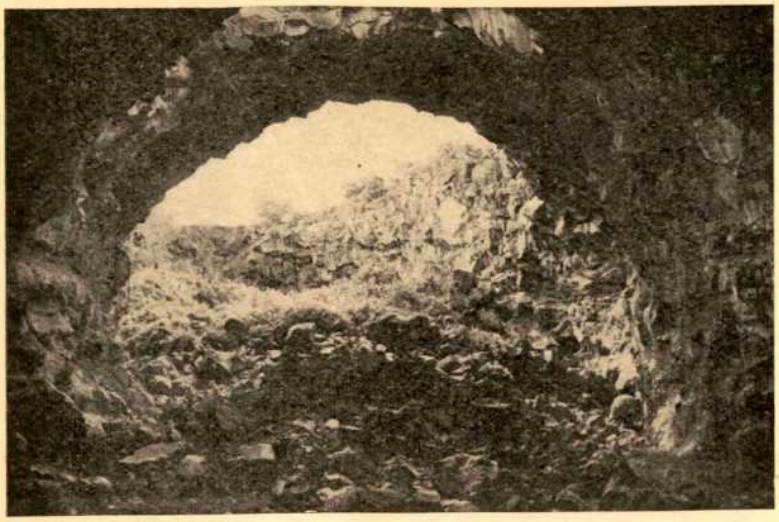

Fig. 1. Entrance to a lava tunnel showing the hole produced by collapse of the roof. The lava blocks in the foreground were derived from recent collapse immediately overhead. (*Photo: L. Wateridge*)

of the collapsed roof (Fig. 1). Smaller accumulations of lava blocks occur at intervals on the floors inside the tunnels and are readily related to early stages of roof collapse immediately overhead. The two tunnels so far investigated clearly represent parts of an originally continuous feature. They are approximately semi-circular in cross-section and attain a maximum height of 20–30 ft. at their entrances. A total length of about 600 yards was examined, one portion extending some 200 yards east of the main hole and the other running westwards. The west tunnel provides a link with a second area of roof collapse and continues for a short distance beyond it before becoming impassable.

Several minor passages were seen entering the main gallery above floor-level and, although at present unexplored, large caverns occur under at least part of the floor. These caverns are locally about 30 ft. deep and undoubtedly represent an earlier tunnel system immediately beneath the one examined. The roofs of the upper tunnels are 20–30 ft. thick and are composed of large irregular lava blocks formed by crude jointing, a feature largely responsible for their ready collapse; in contrast, the lava dividing upper and lower levels is often exceptionally thin. Near the holes produced by roof collapse, soils have been washed into the tunnels to form a smooth flat floor, broken by only occasional outcrops of ropy lava. Away from the tunnel entrances, the floors become more rocky and contain only isolated pockets of soil. A circular hole, some 3 ft. across, occurs on a small updomed portion of the floor of one tunnel, providing a view into a large cavern beneath. The floor at this point is extremely thin, and the bulge and hole give the impression of being explosion features. Minor explosions, caused by the combustion of gases generated from inundated vegetation, have been reported in Hawaii by Wentworth and Macdonald[2]. There, hydrocarbon gases are believed to have accumulated in tunnels in underlying lava and a similar explanation might well apply to the Suswa example.

All the tunnel walls are marked by flow and drip phenomena indicating some mobility of the lava during and after formation of the tubes. These wall features vary in appearance and form; many are stalactitic cones 2–6 in. long with the apices pointing downwards (Fig. 2); others have a fin-like or ropy structure with an approximate vertical orientation. In places, the entire wall crust flowed downwards, arching under at the lower end but retaining a cover of small stalactites.

Distinctive, highly vesicular ropy lava, found along floors and on some walls of the tunnels, is clearly the remnants of the mobile central portion of the flow which evacuated the tube. Some evidently came from overlying flows, entering a cavity beneath through collapsed portions of the roof. Ropy lava which festoons the tunnel walls with flow generally at right angles to stalactitic features represents benches left by subsiding lava in the tube and corresponds to similar occurrences described by Cotton[3]. Locally, aprons of ropy lava are draped over pre-existing ledges on the walls, emphasizing the junctions of individual lava flows and showing that the ropy lava must have been flowing from an upper to a lower tunnel. More convincing evidence of ropy lava flowing into a lower tunnel was seen at one point where the material forming an extremely thin floor apparently cascades into a cavity beneath, the upper tunnel terminating at this locality. Rarely, the ropy lava bears grooves caused by flow against solidified stalactites on the wall. On the other hand, a notable feature of part of one tunnel is a continuous gap about 6 in. wide between the ropy lava forming

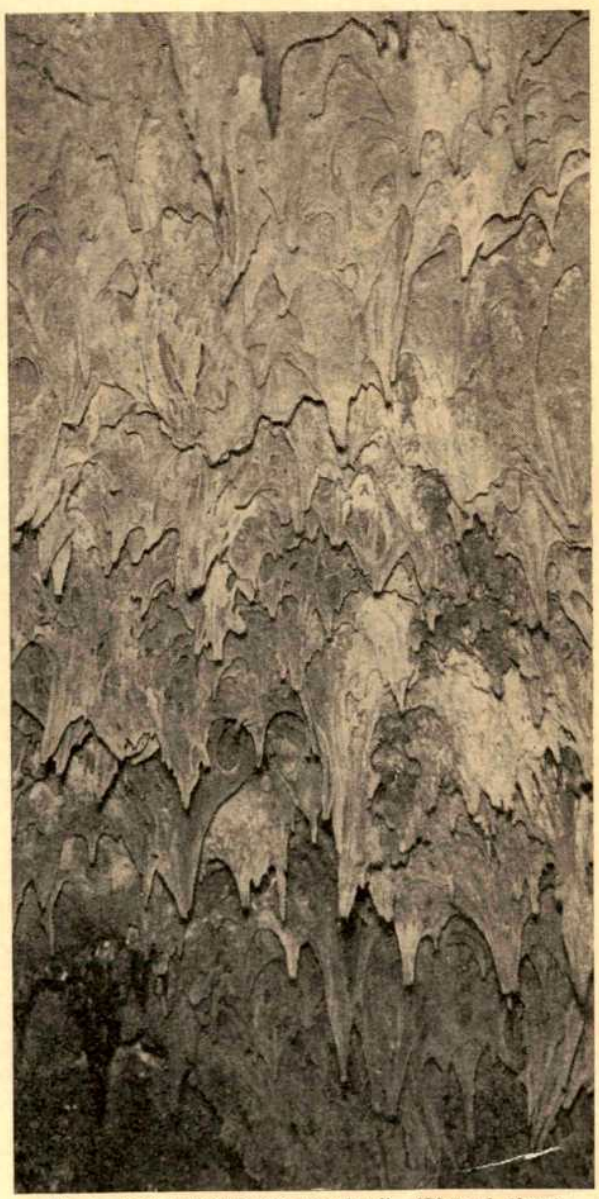

Fig. 2. Lava stalactites on a tunnel wall. (*Photo: J. Glover*)

the floor, and the tunnel walls. The latter continue to bear icicle-shaped stalactites down into the clefts, which are thought to have formed by the inability of the ropy lava to solidify against portions of the walls that had remained hot. The wall stalactites in the gap clearly do not represent 'shark-tooth projections'[2] caused by pulling away of the floor lava from the walls because the surface of the ropy material remains quite smooth. No lava stalagmites were seen in the tunnels examined and is is probably unlikely that any conspicuous ones ever formed judging by the small size of the stalactites. If stalagmites were produced, they have since been obliterated by movement of ropy lava.

The actual formation of lava tubes or tunnels in basaltic lava has been observed in Hawaii[2], where it was found that the process commences with flow in an open channel. A crust quickly forms and, a short distance from the vent, a continuous roof develops and thickens as lava congeals against its under side. Some tubes remain filled; in others the lava drains away to leave open tunnels which range up to 50 ft. in diameter, though only rarely exceeding 20 ft. In Hawaii the main tubes, which may extend for miles, branch into numerous smaller ones, each about 1–3 ft. across, that feed the advancing flow front.

Although the complete pattern of the Suswa tunnels is as yet unknown, it seems remarkable at first sight that they should have developed immediately above each other in successive lava flows. Such an arrangement is readily explained, however, because the dividing lava was thin, allowing the mobile central portion of an overlying flow to drain away through collapsed areas of its floor. Lava flow in open channels, if it ever occurred, probably played only a minor part in the development of these features, and formation of the earliest tunnels probably depended on unusual circumstances, such as extrusion of the lava over patches of hot ground which helped to keep portions of the flow mobile. Steam jets accompanied by small areas of heated ground occur abundantly on Suswa mountain at present. Lava tubes have not been reported from surrounding areas of the Rift Valley where many of the volcanic rocks are phonolites and soda-trachytes similar to those at Suswa. Small tunnels have, however, been noted[4] in Recent basalt flows in the Chyulu range, north-east of Kilimanjaro, and examples described from other parts of the world also appear to have developed primarily in basaltic lavas.

I thank Dr. P. E. Glover, Veterinary Department, Nairobi, for providing the opportunity to examine the tunnels, and also the Commissioner of Mines and Geology, Kenya, for permission to publish this account.

CONCENTRATIONS OF COMMON LEAD IN SOME ATLANTIC AND MEDITERRANEAN WATERS AND IN SNOW

By Dr. M. TATSUMOTO
U.S. Geological Survey, Denver, Colorado
AND
C. C. PATTERSON
California Institute of Technology, Pasadena, California

KNOWLEDGE of lead in the oceans is important not only to investigations of lead isotope evolution in the Earth's crust, but also to those of oceanic and atmospheric mixing. The concentrations of common lead in sea-waters off southern California have been previously examined[1], and were found to decrease abruptly from surface to deep waters. The high concentrations of lead in surface waters were ascribed to industrial contamination, mainly lead tetraethyl aerosols. The work recorded here is an extension of these investigations to the Atlantic and Mediterranean Oceans. Samples of rural snow were also analysed because the finding of high concentrations of lead in such precipitation would validate the view that the oceans have been contaminated by lead tetraethyl aerosols.

Samples of sea-water were collected by means of the stainless steel device used in previous investigations. The sites of the collecting stations are shown in Fig. 1. Because of the extensive use of lead compounds and paints aboard ship, extreme caution was continuously exercised to prevent contamination. Lead in sea-water was assayed by isotope dilution procedures which have been outlined earlier[1].

Snow was collected from central portions of the strata of three separate falls (aggregating about 20 in.) in an open meadow inside the south entrance of Lassen Volcanic National Park. The site was 6 miles from a lightly travelled State highway at an elevation of about 7,000 ft. The branch road had been closed to motor-cars since the time of the first snow fall. Snow was scooped by a stainless steel shovel into a stainless steel funnel, and then forced into polyethylene bottles with a 'Teflon' ramrod. Again, special precautions were taken to prevent contamination. Plastic coverings were worn over outer clothing to minimize contamination from these articles while operations were carried out in the field. The concentration of lead in snow was determined by isotope dilution, the analytical procedure being similar to that used for sea-water. It was necessary to show that lead was not a constituent of dust, therefore the concentration of silica was also determined. This was achieved by adding pure graphite to melted snow in a 'Teflon' beaker, evaporating to dryness, and measuring silicon in the graphite by emission spectrography.

Results of the analyses of sea-water are listed in Table 1. The average error is ± 30 per cent, which is determined

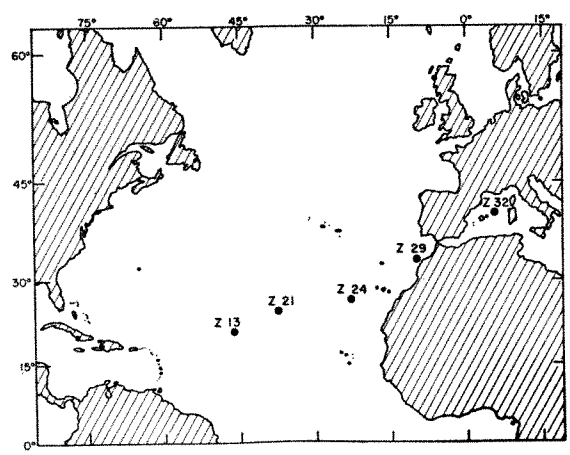

Fig. 1. Location of sampling stations

			2,720	38·411	0·02

* These values are averages of two or more determinations.
† The stations were occupied during the last two weeks in July 1962, on the Atlantic leg of the Scripps Institution of Oceanography *Zyphrus* Expedition.

largely by the amount of contamination lead relative to sample lead. Contamination and reproducibility were determined by multiple analyses of 4- and 8-l. samples from station Z-21. These characteristics were then transferred to other determinations, which were single analyses of either 4 or 8 l. of water. Yields were checked colorimetrically, and analyses associated with aberrant yields were rejected. As discussed previously, this procedure measures dissolved lead only and does not refer to particulate lead.

Results of analyses of 0·01 N hydrochloric acid-soluble lead in snow are shown in Fig. 2. The concentration, as determined by the slope of the regression, is about 2 μg lead/kg snow. In terms of the quantities of snow analysed, this is a very large value, and there is no possibility that it can be ascribed to contamination during collection, transportation, or analysis. No attempt was made to control sample homogeneity, so that in retrospect we are certain that varying amounts of the three falls of snow and of sections within the falls were introduced into our different containers. This unfortunate circumstance probably accounts for the scatter of the individual results and for the spurious contamination intercept, since it is quite possible that the lead content of snow will not only vary from fall to fall, but also will vary during a fall. Except for sample inhomogeneity, the concentration

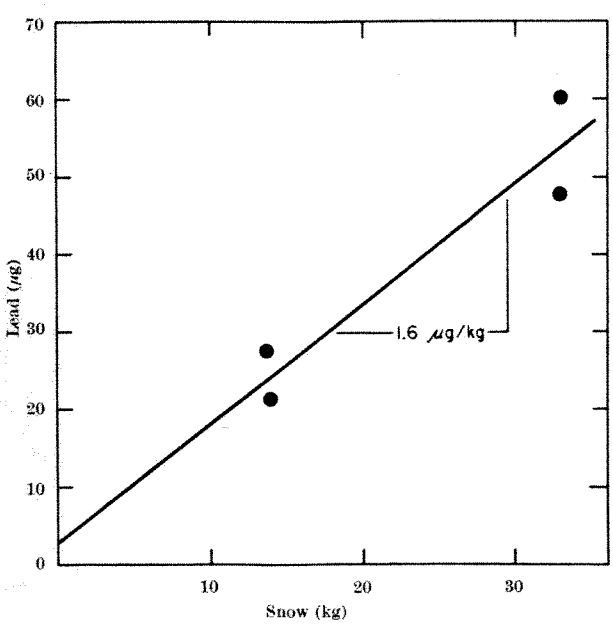

Fig. 2. Concentration of lead in snow. The large scatter in lead values probably results from sample inhomogeneity

analyses of snow should be as accurate as those for sea-water. The isotopic composition of lead from snow was also measured. The values were: $^{206}Pb/^{204}Pb = 18{\cdot}01$; $^{206}Pb/^{207}Pb = 1{\cdot}144$; and $^{206}Pb/^{208}Pb = 0{\cdot}469$. The concentration of total silicon in this snow was 6 μg/kg. This figure is accurate to ± 25 per cent, and can be used as an index of the silicate dust content where silicate dust contains approximately 30 per cent silicon. The average concentration of lead in shale or igneous rock is 15 p.p.m.

In our previous work it was shown that, if the high concentrations of lead observed in a few surface waters of the Pacific were representative of the sea surface of the entire northern hemisphere, the bulk of this lead could be readily accounted for as originating from leaded gasolines. A necessary condition for this point of view is that rain or snow should contain abnormally high concentrations of lead, that is, the concentrations should exceed those which might ordinarily be assigned to silicate dusts. We have found the concentrations of lead and silicon to be about equal in snow collected from a high altitude and 500 miles removed from the Los Angeles complex. In this case, the concentration of lead exceeds that expected from dust alone by a factor of 10^4, which strongly supports the idea of contamination from leaded gasoline exhausts.

Moreover, the concentration of lead measured in snow was found to be 10–100 times larger than those measured in sea-water, so that only a small number of years of such precipitation are required to provide the amount of lead now present in the surface waters of the oceans of the northern hemisphere. The isotopic compositions of lead in surface and deep oceanic waters are not yet known, but the average isotopic compositions of leads precipitated from the oceans at various locations during periods extending throughout the past 10^5 to 10^6 years have been measured[2]. The isotopic compositions of leads in Quaternary pelagic sediments lying within a 1,000 mile-wide strip along the west coast of North America are listed in Table 2.

Table 2. Isotopic Composition of Lead in Pelagic Sediments* and in Snow in the Region of Western North America

Atomic ratio	Range Low	Range High	Mean (of 11 stations)	Snow
206/204	18·63	18·85	18·71	18·01
206/207	1·190	1·203	1·199	1·144
206/208	0·470	0·485	0·483	0·469

* Corrected according to Chow and Patterson (ref. 3).

In this area of the world the composition of a sample of recent snow lead lies far outside the composition-range of oceanic leads deposited during prehistoric times. It seems possible that lead tetraethyl contamination can be used as a tracer in the investigation of oceanic circulation.

The concentration profiles of lead in the Atlantic were found to be different from those in the Mediterranean and the Pacific. This is illustrated in Fig. 3. At the Mediterranean and Pacific stations, lead concentrations are high in surface waters and uniformly low in deeper waters. At the Atlantic stations the concentrations do not follow such a uniform trend with depth, and, in addition, the scatter is confined to considerably smaller values. However, in general, lead concentrations at the Atlantic stations appear to increase from surface to intermediate or deep waters, and then decrease again in very deep or bottom waters. Common lead concentrations in Central North Atlantic surface waters are about 0·05 μg/l. Values in offshore surface waters increase to 0·09 μg/l. near Morocco and to 0·2 μg/l. in the Mediterranean.

There are two different interpretations of these results which can be outlined as follows: (1) the Atlantic stations were thousands of miles from large industrial centres while the Pacific and Mediterranean stations were within a few hundred miles of them, and the two types of concentration profiles might reflect two different degrees of industrial lead contamination, the most natural or least contaminated conditions being represented by the Atlantic profiles; (2) industrial lead contamination, being pervasive but very recent in the oceans, has not appeared in the deep

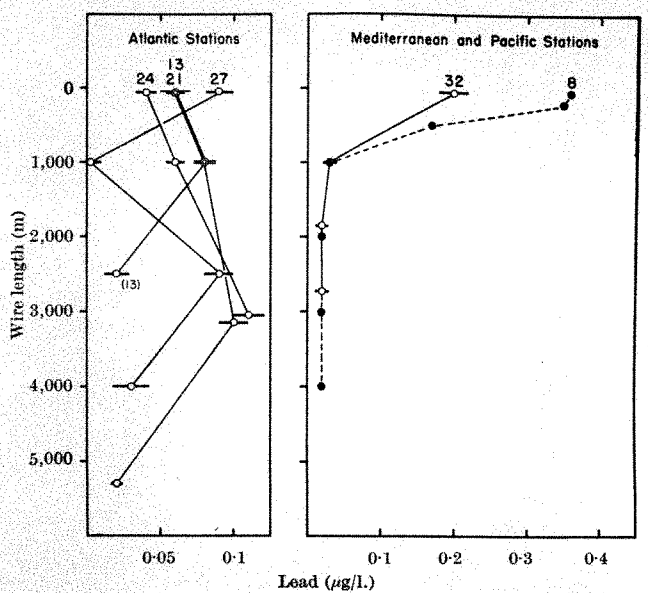

Fig. 3. Lead concentration profiles in the Atlantic and Mediterranean Oceans. Pacific Station (8) is given for comparison (data from ref. 1). The length of the horizontal bar at each point denotes estimated analytical uncertainty. Note the expanded concentration scale for the Atlantic stations

waters of the Pacific and Mediterranean because such waters are centuries old, but it might appear in the deep waters of the Atlantic if such waters are only decades old.

Some investigations suggest that intermediate and deep Atlantic waters may be young. Bowen and Sugihara[4] have found nuclear bomb debris (strontium-90, cerium-144 and promethium-147) to be present in considerable amounts at depths of one thousand metres in the Atlantic. Bowen and Sugihara believed that distribution of strontium-90 shows actual water mass movement and cerium-144 and promethium-147 follow particle settling. It should be pointed out that Miyake *et al.*[5] believed that a high rate of eddy diffusion does account for the bomb debris which they have found at great depth in the Pacific. Broecker[6] reported that he could not find bomb debris at the great depths investigated by Bowen and Sugihara. Perhaps the best arguments for young waters at depth in the Atlantic rest on calculations of current velocities from geostrophic and density effects. Wüst (quoted in ref. 7) estimated minimum velocities of about 500 km/yr. for deep waters originating near the surface at high north latitudes and flowing southward in the North Atlantic. It is this current that could be expected to show high concentrations of common lead at great depths near 20°–30° north latitudes, since it originates at the surface in regions of high precipitation (and lead aerosol contamination) and sinks and flows southward at velocities large enough to convey the effects of contamination occurring within the last decade or so. The 'young water' interpretation of lead concentrations in the Atlantic rests heavily on these latter calculations.

Other investigations suggest that deep Atlantic waters are centuries old, or even older. Koczy[8] found that radium-226 concentrations in the Atlantic doubled from surface to deep waters and he attributed the difference to radioactive decay, since he believes radium-226 in surface waters originates from the sediment-water interface. Koczy estimated turn-over times in the order of one thousand years in the Atlantic. Recently, Koczy (private communication, 1963) calculated a total velocity over the Atlantic of about 5 m/yr. and the turn-over time as 400–600 years. It is possible that the interaction of the biosphere with trace elements such as radium-226 may account for their depletion in surface waters, thus causing over-estimates of turn-over times by this model. Broecker *et al.*[9] observed the depletion of carbon-14 in deep Atlantic waters and interpreted their results so as to yield ages of a few centuries for those waters. It has not yet been shown how these ages can be in error by an order of magnitude. The interpretation of the common lead concentrations in the Atlantic which holds that these are least contaminated by leaded gasoline exhausts depends heavily on the carbon-14 age determinations by Broecker *et al.*[9].

Lead in the surface layers of both the Atlantic and Pacific Oceans may constitute no more than a fourth of all dissolved oceanic lead, so that it can be ignored as an unnecessary complication when the average concentration of common lead in sub-surface Atlantic waters is compared with that in sub-surface Pacific waters. The difference is large enough to merit attention: lead is more concentrated in sub-surface Atlantic waters by a factor of two. This need not be regarded as evidence for rapid 'mixing in' of tetraethyl lead contamination in Atlantic waters. The amount of river run-off entering the Atlantic exceeds that entering the Pacific, and it would be expected that more soluble denudation lead was introduced into the Atlantic before appreciable amounts of lead tetraethyl had been manufactured. In addition, this would be diluted by a smaller volume of sea-water in the Atlantic.

It may be worthwhile to consider whether agricultural stimulation of soluble denudation is responsible for the increase of concentration of lead in deep Atlantic waters. Such effects would appear in waters that are centuries old and might be more pronounced in the Atlantic than in the Pacific. These effects might be small, since it has been estimated[1] that the amounts of additional lead introduced into the oceans as a result of agricultural stimulation are only about one-tenth of the lead introduced to the oceans from lead tetraethyl and other industrial lead chemicals.

The isotopic compositions of dissolved lead in ocean-water have not yet been measured. It is possible that such measurements, when made, will settle some of the issues presented here and provide a better understanding of the nature of oceanic circulation. This should be true because we have found the composition of lead in snow to be very different from the composition of lead which has been deposited on the ocean floors during the past 10^5 years. This is what would be expected if lead in snow was a man-made mixture from a few lead mines instead of a natural mixture from large continental surface areas. It seems very likely that this artificial mixture, added to the oceans during the past three decades, can be used as a tracer for investigating the ocean circulation.

The sea-water samples were collected and spiked by M. Koide and Prof. E. Goldberg of the Scripps Institution of Oceanography. We thank them for their considerable efforts and attention to detail which were required during these operations. Ship time was provided by the University of California, San Diego. C. Bauman of the California Institute of Technology aided in the development of the snow-collecting apparatus. This investigation was supported by American Petroleum Institute project 53 and U.S. Atomic Energy Commission Contract No. *AT*(04–3)–427. Publication has been authorized by the Director, U.S. Geological Survey.

FOSSIL DINOFLAGELLATES FROM UPPER TRIASSIC SEDIMENTS

By Dr. W. A. S. SARJEANT
Department of Geology, University of Nottingham

IN the course of a palynological examination of core samples from the Stowell Park borehole put down for H.M. Geological Survey, Dr. W. G. Chaloner encountered fossil dinoflagellates in a preparation from the Upper Triassic (Rhaetic); these were passed to me for description. Jansonius[1] has described and figured three imperfectly known forms in residues from the Permian and Lower Triassic of western Canada as dinoflagellates: two of these, each based on a single specimen, show a clear transverse furrow and afford faint indication of tabulation, the third being treated as a dinoflagellate on grounds of overall morphology alone. The earliest tabulate dinoflagellates previously known were from the Lower Jurassic (Hettangian) of Denmark[2]. The Stowell Park specimens are the first to be described from the Upper Triassic, and the earliest known dinoflagellates with a determinable tabulation.

The sample was from a depth of 2,059 ft. 2 in. in the borehole put down at Stowell Park, Northleach, Gloucestershire (specimen No. *Bj* 6011; location of borehole, Ordnance Survey, 7th Edition, One-Inch Sheet 235, National Grid reference *Sp* 08351173), the stratigraphy of which was described in 1956 [3]. It consisted of greenish calcareous sandstone from a position in the Cotham Beds, 1 ft. above typical marine shales with *Pteria contorta* and 4 ft. below marls with '*Estheria*'. The microfossils here described are contained in slide number *P.S.* 1983, in the collections of H.M. Geological Survey; they are stained with safranin and mounted in glycerine jelly.

More than 120 complete or partial shells, attributable to two new species, were found. Complete shells are relatively few in number; in both species, rupture of the theca after encystment occurred just above the anterior margin of the transverse furrow, the greater part of the epitheca being thrown off; the bulk of the specimens comprise either epithecæ or hypothecæ with transverse furrow. A numerical analysis of 100 incomplete shells produced the following result:

Gonyaulax rhaetica sp. nov. Epithecæ 27.
Hypothecæ with transverse furrow 37.
Gonyaulax chaloneri sp. nov. Epithecæ 10.
Hypothecæ with transverse furrow 26.

The proportionately greater number of hypothecæ probably merely reflects a tendency of the epithecæ, when thrown off, to become so damaged as to be unrecognizable.

This method of archæopyle formation, by breakage immediately anterior to, and not along, the transverse furrow, has not previously been described (cf. ref. 4).

Systematic Description of Species.

CLASS DINOPHYCEAE
Family Gonyaulaceae
Genus *Gonyaulax* Diesing
Gonyaulax rhaetica sp. nov.
Figs. 1 and 2 (left)

Diagnosis. A species of *Gonyaulax* having a spindle-shaped shell, with a cover of coarse granules or very short spines, absent from the furrows. Transverse furrow broad, lævorotatory; longitudinal furrow narrow on the epitheca but broadening considerably as it approaches the antapex. Low ridges outline the following tabulation—four apical plates (1–4′), with plate 1′ elongate and situated in the anterior prolongation of the longitudinal furrow; one anterior intercalary plate (1*a*); six pre-equatorial

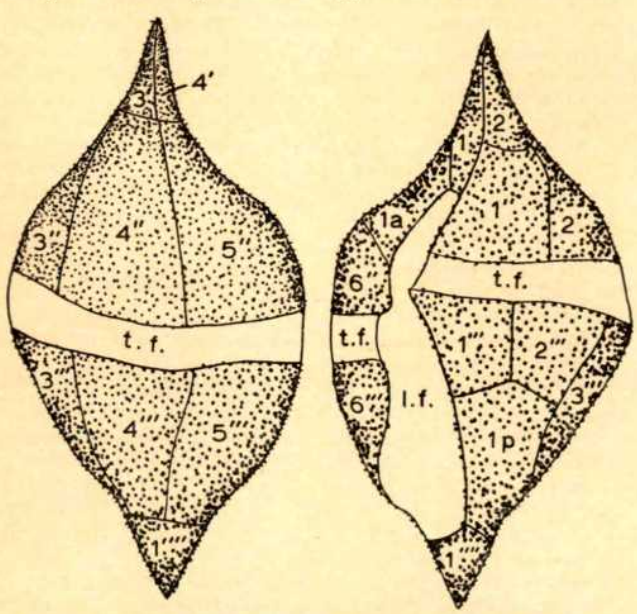

Fig. 1. *Gonyaulax rhaetica* sp. nov. Left, in dorsal view; right, in ventral view. Sketch based on the holotype and numerous paratypes. *t.f.*, transverse furrow: *l.f.*, longitudinal furrow

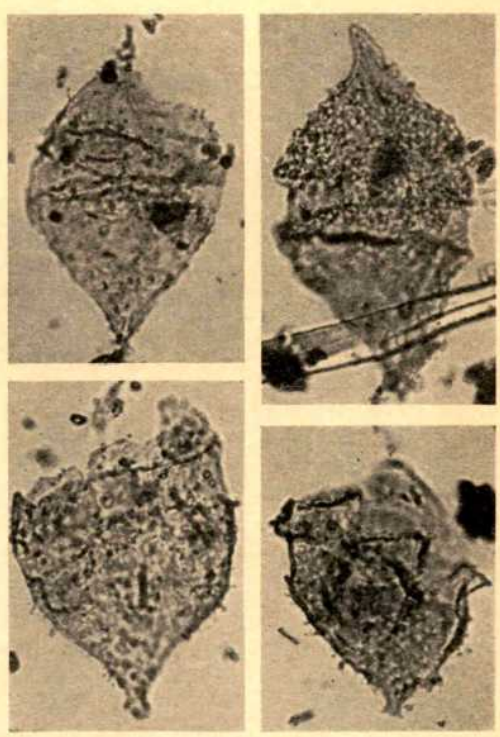

Fig. 2. Top left, *Gonyaulax rhaetica* sp. nov.: the holotype, in dorsal view; bottom left, *G. rhaetica* sp. nov.: a paratype, lacking the epitheca; top right, *Gonyaulax chaloneri* sp. nov.: the holotype, in oblique ventral view; bottom right, *G. chaloneri* sp. nov.: a paratype, lacking the epitheca

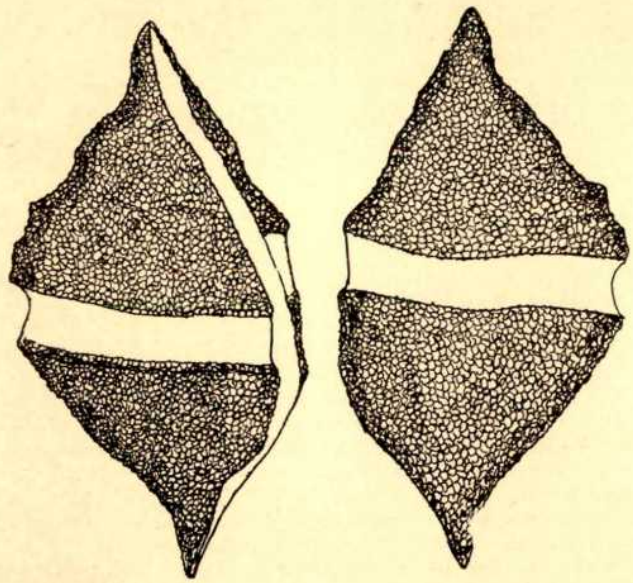

Fig. 3. *Gonyaulax chaloneri* sp. nov. Left, in oblique dorsal view; right, in oblique ventral view. Sketch based on the holotype

plates (1–6″); six post-equatorial plates (1–6‴), plates 1‴ and 2‴ being reduced and quadrate; one posterior intercalary plate (1*p*); and one antapical plate (1⁗).

Holotype. Specimen 98, slide *P.S.* 1983. *Dimensions.* Holotype; length 65μ, breadth 40μ. Estimated range; length 60–90μ (based on complete specimens and on probable original size of incomplete specimens). *Number of Specimens*, 75.

Derivation of Name. Named after the Rhætic Stage of the Triassic, in which this assemblage occurs.

Remarks. Gonyaulax rhaetica differs in its combination of symmetry and tabulation from all other described fossil species.

Gonyaulax chaloneri sp. nov.

Figs. 2 (right) and 3.

Diagnosis. A species of *Gonyaulax* having a spindle-shaped shell with a dense reticulate ornamentation formed by low ridges on the shell surface; this ornament is absent from the furrows. Transverse furrow very broad, lævo-rotatory; longitudinal furrow narrow, extending from apex to antapex. A tabulation is suggested but was not capable of determination, even in approximate terms, in any specimen seen.

Holotype. Specimen 43, slide *P.S.* 1983. *Dimensions.* Holotype; length 75μ, breadth 39μ. Estimated range: length 50–80μ (based on complete specimens and on probable original size of incomplete specimens). *Number of Specimens*, 45.

Derivation of Name. Named in honour of Dr. W. G. Chaloner, Department of Botany, University College, London.

Remarks. Gonyaulax chaloneri differs in its combination of symmetry and shell ornament from all other described fossil species. In absence of a determinable tabulation, its attribution to *Gonyaulax* was made largely on the basis of comparable symmetry and manner of pylome formation to *G. rhaetica*. Species of *Gonyaulax* having a reticulate ornament, but quite different in shell shape, have been described previously, for example, *G. areolata* Sarjeant[5].

I thank the Director of the Geological Survey for permitting description of these forms. I also thank Dr. F. W. Anderson and Dr. W. G. Chaloner for their help and advice.

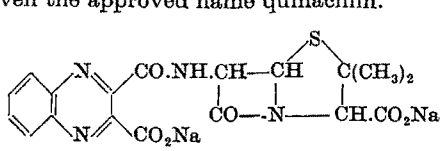
QUINACILLIN: A NEW PENICILLIN WITH UNUSUAL PROPERTIES

By Dr. H. C. RICHARDS, Dr. J. R. HOUSLEY and Dr. D. F. SPOONER
Chemistry and Biology Divisions, Research Department, Boots Pure Drug Co., Nottingham

ACYLATION of 6-aminopenicillanic acid (6-APA)[1] has provided a number of clinically effective, semi-synthetic penicillins[2] some of which are resistant to hydrolysis by staphylococcal penicillinase. In the course of a programme concerned mainly with heterocyclic side-chain penicillins, we noted at an early stage that 2-pyridylpenicillin (I) was inactivated more slowly than was benzylpenicillin by staphylococcal penicillinase and was more active against moderately benzylpenicillin-resistant strains of *Staphylococcus aureus* than were the 3-pyridyl-, 4-pyridyl- or phenyl-analogues. Alkyl substituents in the pyridine ring had little effect on the activity but in the case of the 5,6-benzo-derivative, 2-quinolylpenicillin (II), the activity was increased against both sensitive and moderately resistant strains.

Concurrently, efforts had been directed towards the preparation of *bis*-penicillins, particularly from vicinal dicarboxylic acids, on the supposition that the two penicillanic acid moieties might provide mutual steric protection against penicillinase attack. In apparent agreement with this hypothesis, the penicillins prepared from pyridine-2,3-, pyrazine-2,3-, and 5,6-dimethylpyrazine-2,3-dicarboxylic acids by the mixed anhydride method[3], using two equivalents of ethyl chloroformate and of 6-APA, had significant activity against highly resistant strains of *Staphylococcus aureus*. Where the carboxy-groups were non-vicinal, as in pyridine-2,6-, pyridine-2,5-, and pyrazine-2,5-dicarboxylic acids, the derived penicillins were of low activity. It was expected by analogy with (I) and (II) that the penicillins (III) and (IV) derived from quinoline-2,3-dicarboxylic acid and quinoxaline-2,3-dicarboxylic acid, respectively, would show a much enhanced activity and this expectation was fully realized (Table 1).



Further investigation into the application of the mixed anhydride method to the preparation of penicillins from vicinal dicarboxylic acids showed that the supposed *bis*-penicillins (III) and (IV) were in fact mixtures of mono-penicillins. In a model experiment, *bis*-triethylammonium phthalate (1 mol) in tetrahydrofuran was reacted with ethyl chloroformate (2 mol), triethylammonium chloride removed, and the filtrate reacted with *cyclo*hexylamine to give *N-cyclo*hexylphthalamic acid[4] with no trace of *N,N′*-di*cyclo*hexylphthalamide[5]. Furthermore, low-temperature (5°) evaporation of the filtrate before treatment with *cyclo*hexylamine afforded only phthalic anhydride and diethyl pyrocarbonate[6]. Similarly, quinoline-2,3- and quinoxaline-2,3-dicarboxylic acids gave the corresponding cyclic anhydrides and diethyl pyrocarbonate. The reaction conditions used in the preparation of (III) and (IV) would therefore be expected to give mixtures of ethoxypenicillin, derived from diethyl pyrocarbonate, and the carboxy-mono-penicillin derived from the cyclic anhydride. Evidence from paper chromatograms (butan-1-ol (4) : ethanol (1) : water (5), Whatman No. 1) supported these conclusions. Paper chromato-

Table 1. ACTIVITY OF SOME HETEROCYCLIC PENICILLINS AGAINST *Staphylococcus aureus*

Penicillin side-chain acid	Penicillin	M.I.C.* μg/ml.		
		Highly penicillin-resistant	Moderately penicillin-resistant	Penicillin-sensitive
Phenylacetic	Benzyl	> 500	33·3	0·01
Pyridine-2-carboxylic	I	500	11·1	0·4

* Minimum inhibitory concentrations, tested by serial dilution in peptone, yeast-extract agar; surface-inoculated and incubated for 24 h at 37°.
† Prepared by Dr. N. W. Bristow.

graphy of the crude quinoline-derivative (III) gave a bioautograph with three zones of inhibition, R_F 0·20, 0·45, and 0·60, against a benzylpenicillin-sensitive strain ('Dakin') of *Staphylococcus aureus*. Only the two zones, R_F 0·20 and 0·45, were observed when the test organism was a benzylpenicillin-resistant strain (N.C.T.C. 8452) of *Staphylococcus aureus*. Similarly, the crude quinoxaline-derivative (IV) gave two zones, R_F 0·12 and 0·60, against 'Dakin' but only the one zone, R_F 0·12, against '8452'. The zone of inhibition, R_F 0·60, was attributed to ethoxypenicillin since an authentic sample, prepared from ethyl chloroformate and 6-APA, had the same R_F and was inactive against *Staphylococcus aureus* 8452. (In agar dilution tests, ethoxypenicillin did not inhibit highly-resistant strains of *Staphylococcus aureus* and was active against sensitive strains only at concentrations greater than 10 μg/ml.) Quinoxaline-2,3-dicarboxylic anhydride reacted with 6-APA to give a single product, 3-carboxy-2-quinoxalinylpenicillin, R_F 0·12 ('Dakin' or '8452'), while the unsymmetrical quinoline-2,3-dicarboxylic anhydride gave a mixture of two products, R_F 0·20 and 0·45, presumably the isomeric 2-carboxy-3-quinolyl- and 3-carboxy-2-quinolyl-penicillins. The products from the cyclic anhydrides were highly active and accounted for the activities of the mixtures (III) and (IV) against *Staphylococcus aureus* 8452. The penicillins from both the cyclic anhydrides were of sufficient potential interest to merit clinical assessment. However, 3-carboxy-2-quinoxalinylpenicillin offered considerable advantages because of its accessibility and its freedom from the complication of isomerism presented by the quinoline analogue. The disodium salt (V) was selected as the most suitable form for medical and veterinary use and has been given the approved name quinacillin.

V

Quinacillin is prepared readily by the condensation of quinoxaline-2,3-dicarboxylic anhydride with 6-APA in dimethylformamide and triethylamine[7]. The product separates from acetone as the *bis*-triethylammonium salt monohydrate, m.p. 135°–137° (decomp.), $[\alpha]_D^{20}$ + 142° (c, 0·376 in water) (found: C, 56·3; H, 7·4; N, 13·4; S, 5·1; H_2O, 3·3; $(C_2H_5)_3N$, 31·4. $C_{30}H_{46}N_6O_6S$, H_2O requires C, 56·6; H, 7·55; N, 13·2; S, 5·0; H_2O, 2·8; $(C_2H_5)_3N$, 31·7 per cent). Treatment of an aqueous solution of the *bis*-triethylammonium salt with saturated aqueous sodium acetate gives quinacillin as cream needles, m.p. about 260° (decomp.), usually containing about 9 per cent water after drying *in vacuo* at 40° (found: C, 42·7; H, 4·3; N, 11·3; S, 5·9; H_2O, 9·2. $C_{18}H_{14}N_4Na_2O_6S$ with 9·2 per cent water requires C, 42·6; H, 3·8; N, 11·05; S, 6·3 per cent), λ_{max} 242 (ε, 32,100) and 326 mμ (ε, 7,280), ν_{max} 3,440, 1,759, 1,692, 1,596, 1,524, 1,415, 1,323 and 779 cm^{-1} (potassium bromide disk). Anhydrous quinacillin, obtained by drying at 100°/2 mm, m.p. 261°–262° (decomp.) and $[\alpha]_D^{23}$ + 183·5° (in water) (found: C, 47·0; H, 3·3; N, 12·1. $C_{18}H_{14}N_4Na_2O_6S$ requires C, 46·95; H, 3·0; N, 12·2 per cent), is very hygroscopic. There is little definite evidence for the formation of any true hydrate, and as much as 30 per cent of water may be taken up at 21° depending on the relative humidity. Quinacillin acquires a bright yellow colour on exposure to strong sunlight but is stable at 100° for at least 3 months. It is freely soluble in water and a 25 per cent aqueous solution is stable for 2 months at 0° and has a half-life of 12 days at 37° (hydroxylamine assay). The half-life in solution in 50 per cent ethanolic 0·1 N hydrochloric acid is 290 min (hydroxylamine assay). This very high acid stability is consistent with the presence in quinacillin of an electron-attracting group situated β to the side-chain amide carbonyl group as in ampicillin and other acid-stable penicillins[8]. Quinacillin gives a deep violet chelate with ferrous ions and a red colour with cuprous ions.

For a penicillin, quinacillin has some unusual properties. Thus, antimicrobial activity is highest against *Staphylococcus aureus* and both antimicrobial activity and rate of diffusion in agar are enhanced as the *p*H of the medium is decreased. The induction of staphylococcal penicillinase formation in the one strain tested is surprisingly low.

The bacteriostatic activity of quinacillin is summarized in Table 2. It is clear that this penicillin is more active against *Staphylococcus aureus* than against any other microbial species tested.

Table 2. BACTERIOSTATIC ACTIVITY OF QUINACILLIN
(Serial dilutions in agar* surface-inoculated with 0·01 ml. of appropriate overnight cultures; incubated for 24 h at 37°)

Organism	M.I.C. μg/ml.
Staphylococcus aureus (see Table 3)	0·15–0·62

Shigella (3 species)	> 100
Pseudomonas (2 species)	> 100

* Peptone. yeast-extract, glucose agar, *p*H 7·0, containing 10 per cent v/v ox serum.

The penicillin is not highly bound to serum proteins. Bacteriostatic activity is not depressed by more than one two-fold dilution when citrated human blood is incorporated in nutrient agar at a concentration of 50 per cent (v/v). A similar result is obtained in serial dilution tests against *Staphylococcus aureus* when ox serum at a concentration of 10 or 50 per cent is added to 'Oxoid' nutrient broth. In equilibrium-dialysis experiments with the penicillins at initial concentrations of 1 mg/ml. in ox-serum, about 20 per cent of quinacillin, compared with about 35 per cent of benzylpenicillin, was bound to the non-dialysable fraction.

The activity of quinacillin is enhanced as the *p*H of the medium is lowered over a *p*H range compatible with growth. In agar-dilution tests the minimum inhibitory concentrations (M.I.C.) for 20 strains of *Staphylococcus aureus* fell from 0·62–0·15 μg/ml. at *p*H 7·5, to 0·15–0·03 μg/ml. at *p*H 5·5. Using various nutrient agars at *p*H 7·0, concentrations of quinacillin below 10 μg/ml. could not be assayed by diffusion against a variety of test organisms, presumably because the penicillin diffuses poorly in agar at this *p*H. However, when nutrient agar is buffered at *p*H 5·3, concentrations of quinacillin as low as 0·1 μg/ml. give measurable zones of inhibition when *Staphylococcus aureus* is used as the test organism.

In Table 3 the inhibitory activity of quinacillin against 50 strains of *Staphylococcus aureus* obtained from clinical sources is compared with that of benzylpenicillin.

Table 3. Bacteriostatic Activity of Quinacillin against 50 Strains of *Staphylococcus aureus* from Clinical Sources

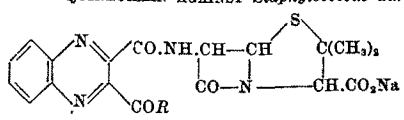
Benzylpenicillin	6	0	0	0	0	1	2	41

* Serial dilution in agar, *p*H 7·0.

The new penicillin is highly inhibitory to both penicillin-sensitive and penicillin-resistant strains of this organism. Replicates[9] from agar-dilution tests and sub-cultures from serial dilution tests in broth indicate that, as with other penicillins, quinacillin is bactericidal to growing cells. The M.I.C. is not significantly altered in serial dilution tests in broth against *Staphylococcus aureus* when the number of penicillinase-producing cells in the inoculum is varied one thousand-fold. This indication of high resistance to staphylococcal penicillinase was confirmed by manometric measurements[10]. The rate of hydrolysis of quinacillin at *p*H 7·0 and 37° by staphylococcal penicillinase was determined using *Staphylococcus aureus* (Parker) cultures which had been induced to form high levels of the enzyme with methicillin (0·5 μg/ml.) in casein hydrolysate medium. Significant hydrolysis of quinacillin was not detected over a period of 4 h when the penicillin (25 μmoles) was incubated with 60 units of enzyme activity (1 unit hydrolyses 1 μmole of benzylpenicillin per hour under these conditions). Using higher concentrations of cell-bound enzyme, preliminary iodometric determinations[11] indicated that the K_m of the penicillin at *p*H 6·5 is about 5 mg/ml. compared with 7 μg/ml. for benzylpenicillin[12] and about 8 mg/ml. for methicillin[12,13]. At high substrate concentration, when the enzyme is saturated, the rate of hydrolysis (V_{max}) of quinacillin is about 5 per cent of that for benzylpenicillin. However, because of the low affinity of quinacillin for penicillinase it is inactivated much more slowly at lower concentrations[12].



At low concentrations in casein hydrolysate medium quinacillin is a relatively poor inducer of penicillinase synthesis in *Staphylococcus aureus* (Parker) despite the high inhibitory activity of the compound and its resistance to penicillinase. The induction constant[14] (about 5 μg/ml.) is about 25 times greater than that for methicillin in this system. Benzylpenicillin gives low and variable results due to its rapid destruction[12,13].

Quinacillin, like other penicillins, is virtually non-toxic to animals and has proved effective in the treatment of staphylococcal infections when administered parenterally. Although highly acid-stable it is poorly absorbed by the oral route and absorption appears to vary in different species of animals.

Quinoxaline-2,3-dicarboxylic acids disubstituted symmetrically in the benzene ring are not readily accessible. Only two, 6,7-dimethyl- and 6,7-dichloro-quinoxaline-2,3-dicarboxylic acids, were prepared and converted into the corresponding penicillins. Activity (Table 1) was decreased markedly compared with quinacillin.

Several related penicillins were made from half-esters and half-amides (prepared from the anhydride with the appropriate alcohol or amine) of quinoxaline-2,3-dicarboxylic acid. The lower alkyl esters had activity against resistant staphylococci comparable with that of quinacillin but activity decreased with increasing chain length or chain branching. The amides were less active than quinacillin against resistant staphylococci (Table 4).

* Serial dilution in agar, *p*H 7·0.
† As Table 1.

Replacement of the 3-carboxy-group of quinacillin with hydrogen or with chloro-, hydroxy-, ethoxy-, piperidino- or 1,2,3,4-tetrahydro-1-quinolyl-groups virtually eliminated activity against highly resistant staphylococci. However, activity in the quinoline series was retained when the side-chain carboxy-group was replaced with phenyl. In our experience this behaviour has some parallel in the monosubstituted phenylpenicillin series and only *o*-carboxyphenylpenicillin (and derived side-chain amides)[15] and *o*-biphenylylpenicillin[16] have been described as having useful activity against resistant staphylococci. 3-Carboxy-2-naphthylpenicillin, isosteric with quinacillin, has similar microbiological activity but is unstable to acid (half-life 9 min, at 37° in 50 per cent ethanolic 0·1 N-hydrochloric acid).

Penicillins derived from a number of other vicinal dicarboxylic acids containing a five-membered heterocyclic ring, for example, benzofuran-2,3-dicarboxylic acid, 5-methylisoxazole-3,4-dicarboxylic acid and pyrazole-3,4-dicarboxylic acid, were inactive against resistant staphylococci.

We thank Drs. D. A. Peak and G. Woolfe for their encouragement, and those of our colleagues who gave assistance.

ACTINOMYCIN D AND VACCINIA VIRUS INFECTION OF HELA CELLS

By AARON J. SHATKIN

Cell Biology Section, Laboratory of Biology of Viruses, National Institute of Allergy and Infectious Diseases, Bethesda 14, Maryland

INHIBITION of synthesis of DNA by 5-fluorodeoxyuridine[1] or of formation of RNA by actinomycin *D* (C_1)[2] prevents the replication of vaccinia virus in tissue culture cells. It has been reported that, when DNA synthesis is blocked, viral protein formation proceeds[3]. It seemed of interest, then, to examine the effect of RNA suppression by actinomycin on viral protein synthesis.

The procedures utilized for the growth and infection of HeLa *S*3-1 cells with strain *WR* vaccinia virus, the plaque assay for infectious virus[4], and the indirect immunological precipitation of radioactive viral protein[3,5,6] have already been described.

The formation of infectious vaccinia virus in suspension cultures of HeLa *S*3-1 cells is more than 99 per cent inhibited by 0·1γ actinomycin/ml. added 1½ h after infection (Table 1). Furthermore, treatment of cells prior to infection with 2γ actinomycin/ml., a concentration which limits RNA synthesis within 1 h to less than 2 per cent the normal rate, results in an almost complete block in viral protein synthesis (Fig. 4). Conversely, when RNA formation is similarly blocked in uninfected cells, protein synthesis continues at an optimal rate for 5 h followed by a diminished rate for at least another 7 h (Fig. 1). To examine whether renewal of RNA in infected cells is necessary for continued viral protein synthesis, 2γ actinomycin/ml. was added to a suspension culture at 5 h after infection, a time when only viral protein synthesis is proceeding rapidly. Within 1 h after addition of actinomycin, protein synthesis stopped (Fig. 2).

Table 1. ACTINOMYCIN INHIBITION OF INFECTIOUS VIRUS SYNTHESIS

Actinomycin concentration (γ/ml.)	Virus titre (PFU/ml.)
—	3×10^8
0·01	$2{\cdot}8 \times 10^8$
0·1	2×10^3
0·5	$< 10^3$

Actinomycin at the concentrations shown was added 1½ h after infection to replicate suspension cultures containing 2 × 10^5 HeLa cells per ml. Virus titres were determined after 19 h. The control culture contained 2×10^8 PFU/ml. at 3 h after infection.
PFU, plaque-forming units.

It has been reported previously that the synthesis of protein(s) less than 1 h prior to virus maturation is necessary for infectious virus formation[4]. Therefore, the interruption of viral protein synthesis by actinomycin might be expected to interrupt whole virus synthesis within this interval. As seen in Table 2, virus production is blocked within 1 h when actinomycin is added 5 h following infection. The maturation process remains sensitive to the antibiotic throughout the infectious cycle (Fig. 3). Addition of actinomycin at 3½ h after infection, 1 h before the onset of maturation, blocks subsequent infectious virus formation completely. Inhibition also occurs within 1 h when actinomycin is added at 11 h after infection. At this time a full yield of viral DNA[1] and most of the viral protein[3] have been synthesized.

Table 2. INTERRUPTION OF VIRUS MATURATION BY ACTINOMYCIN

Hours after infection	Virus titre (PFU/ml.) Control	Actinomycin
3	$3{\cdot}2 \times 10^4$	$3{\cdot}2 \times 10^4$
5	$1{\cdot}1 \times 10^5$	$1{\cdot}1 \times 10^5$
5½	—	$1{\cdot}5 \times 10^5$
6	—	$2{\cdot}7 \times 10^5$
7	$7{\cdot}6 \times 10^5$	$2{\cdot}7 \times 10^5$
8½	2×10^6	$2{\cdot}4 \times 10^5$
12	4×10^6	$2{\cdot}2 \times 10^5$

At 5 h after infection, the suspension culture was divided, and one of the resulting cultures received 2γ actinomycin/ml. At the indicated times, samples were removed from each and assayed for infectious virus titre.

The formation of cell proteins diminishes following vaccinia virus infection of HeLa cells (Fig. 4). During the first 4 h of infection the rate of protein synthesis is rapid, and viral proteins comprise 30–40 per cent of the total protein synthesized. From the fourth hour on, the total protein synthetic rate parallels that observed for viral protein formation, and after this time in the infectious cycle no net increase in cell protein occurs. The inhibition of cell protein formation by infection is not dependent on the continued synthesis of viral products. Net cell protein synthesis stops at 4 h after infection even when the formation of RNA, viral proteins, and viral DNA[2] has been blocked by treatment of the cells with actinomycin beginning 1 h prior to infection (Fig. 4).

Vaccinia virus infection of HeLa cells leads to a sharply decreased, although continued, rate of incorporation of

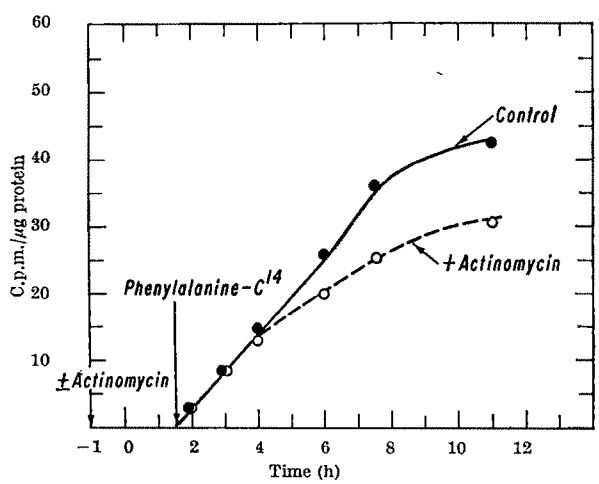

Fig. 1. Continued protein synthesis in uninfected cells in the presence of actinomycin. Actinomycin, 2γ/ml., was added to one of two suspension cultures of 2×10^5 cells/ml. After 1 h at 37° C, the cells were treated as described in the legend to Fig. 4, but without the addition of virus. Following phenylalanine-^{14}C addition (0·01 mM, 2 μc./μM), samples were removed, extracted twice with cold 5 per cent trichloroacetic acid, defatted and hydrolysed with 1 N potassium hydroxide. An aliquot of the hydrolysate was counted and another used to determine total protein[5]

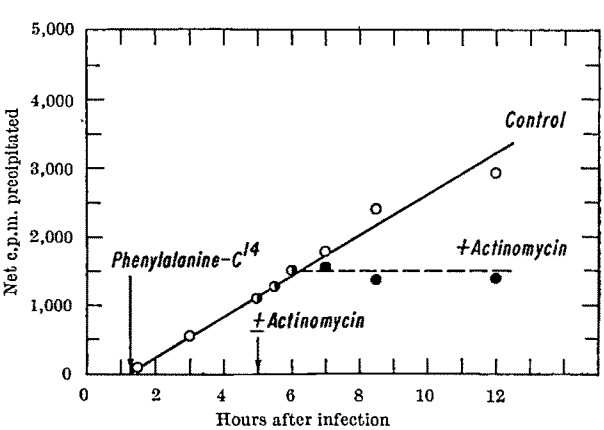

Fig. 2. Inhibition of viral protein synthesis by actinomycin. A suspension culture received phenylalanine-^{14}C at 1½ h after infection. At 5 h the culture was divided and 2γ actinomycin/ml. added to one of the resulting cultures. The incubation was continued, and samples removed from each at the indicated times were assayed for viral protein by immunological precipitation

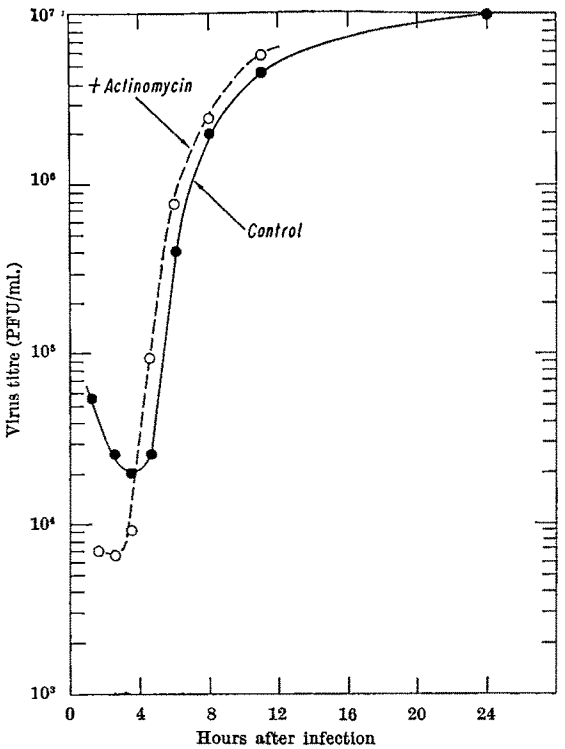

Fig. 3. Inhibition of infectious virus formation by actinomycin. A series of replicate cultures of infected cells was established at a cell concentration of 2×10^5/ml. One culture was sampled at increasing intervals after infection to obtain the infectious virus growth curve which is designated 'control'. At the indicated time after infection, one culture of the series received 0·5γ actinomycin/ml. At 24 h after infection, all inhibited cultures were assayed for infectious virus. The curve labelled 'actinomycin' represents the 24-h virus yields obtained when actinomycin was added at the times indicated by the position of the points on the curve

uridine into acid-insoluble material (Table 3)[7]. The observed reduction in total RNA synthesis may reflect a decrease in cell RNA formation together with an increase in the synthesis of virus-related RNA. Both the base composition and site of synthesis of the RNA made by vaccinia-infected cells are of interest in view of the cytoplasmic formation of both viral DNA and proteins[8]. A decrease in cell RNA synthesis would not by itself explain the cessation of cell protein synthesis in vaccinia-infected

Table 3. Reduction in RNA Synthesis after Vaccinia Infection

Hours after infection	Total CPM incorporated	% of maximum
Uninfected	2,310	100
2	2,110	91
4	1,400	61
7	730	32

At the indicated times after infection, one of a series of replicate suspension cultures each containing 100 ml. of cells at a concentration of 2×10^5/ml. received 2×10^{-5} M uridine-^{14}C (specific activity = 0·56 μc./μM). After 30 min the culture was chilled and the amount of uridine-^{14}C incorporated into RNA was determined[10].

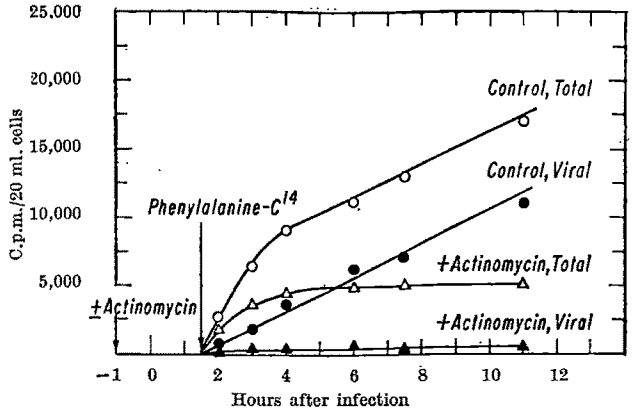

Fig. 4. Inhibition of cell protein synthesis following virus infection. One of two suspension cultures containing 2×10^5 cells/ml. was treated with 2γ/ml. actinomycin for 1 h at 37°. Each was then concentrated ten-fold, infected with an input multiplicity of 10–20 PFU/cell, washed twice in phenylalanine-deficient Eagle's medium[11] containing 20 per cent dialysed human serum, and resuspended to 2×10^5 cells/ml. in deficient medium plus 5 per cent dialysed horse serum. Actinomycin was present throughout. At 1½ h after infection, 0·01 mM phenylalanine-^{14}C (specific activity = 2 μc./μM) was added and the incubation continued at 37° C. Samples were removed at time-intervals and centrifuged. Total radioactivity incorporated into protein was determined following cold 5 per cent trichloroacetic acid extraction and solubilization in 1 N potassium hydroxide of an aliquot of each sample. Viral protein was measured by immunological precipitation of a second aliquot

cells, since protein synthesis in uninfected cells continues for 12 h or longer when RNA formation has been 98 per cent inhibited by actinomycin (Fig. 1). The finding that synthesis of cell protein decreases even when viral products are not formed in infected cells suggests that the infecting virus inhibits the ability of the RNA synthesized prior to infection to support cell protein formation. In the presence of the antibiotic only the inhibition of cell protein synthesis may occur. In its absence, the synthesis of virus-related RNA could proceed and might then direct the synthesis of viral proteins.

The foregoing observations suggest that a vaccinia virus DNA-directed RNA is synthesized in infected HeLa cells and that its synthesis throughout infection is necessary for continued viral protein and infectious virus production. Information now being sought concerning the cellular site of synthesis and chemical nature of this RNA may provide a better understanding of the processes by which virus re-directs the metabolism of cells.

A POSSIBLE CASE OF GENETIC ASSIMILATION OF BEHAVIOUR

By Dr. NEVILLE MORAY
Department of Psychology, University of Sheffield
AND
KEVIN CONNOLLY
Department of Psychology, Birkbeck College, London

Clutterbuck and Beardmore[1] recently reported that if *Drosophila melanogaster* is reared on a medium adulterated with a substance to which they are aversive, such as peppermint oil, then the behaviour of the flies may alter so that they become less aversive to the adulterant. These authors found that flies reared on peppermint-flavoured medium for six generations became less averse to that substance, both measured by the relative numbers of eggs laid on it compared with the number laid on a normal medium, and also in terms of the number of flies

found on peppermint food rather than on normal food in a choice situation.

The method of testing which they used is not sensitive, owing to the great discrepancy in the number of eggs laid by different pairs of flies. We have found that in single pair matings the number of eggs laid may vary from zero to more than 100 in flies randomly picked from the same population. Hence their egg-laying results could be due to abnormal fertility in one or two flies, which could more than counterbalance a low egg-laying score on normal food by the majority. Further, their food choice test was performed over periods of 1 h and 24 h, and it is likely that with the volatile oils which they used for adulterants there would have been a considerable spread of the adulterant throughout the apparatus in that time. Their results are, however, suggestive, and we have repeated their experiment with a different design.

A stock of wild-type *Drosophila melanogaster* (Pacific) strain was kindly provided by the Department of Zoology, University of Edinburgh. These were divided into the groups shown in Table 1.

Table 1

AN	Flies averse to peppermint reared on normal food
NAN	Flies non-averse to peppermint reared on normal food
UN	Unselected flies reared on normal food
AP	Flies averse to peppermint reared on peppermint food
NAP	Flies non-averse to peppermint reared on peppermint food
UP	Unselected flies reared on peppermint food

From this Table is will be seen that there was artificial selection for aversion or non-aversion to the adulterant, and natural selection by the presence or absence of adulterant in the food. Artificial selection was carried out in the apparatus shown in Fig. 1. Flies were placed in the chamber *P* and the door *D* opened. After 2 min, *D* was closed. If aversive flies were being selected those which remained in *P* were removed, the remainder replaced in *P*, and the process repeated. This was done 5 times. The remaining flies were used as the 'aversive' (*A*) stock. If non-aversive flies were required, the flies remaining in *P* were retained each time. Each artificially selected line was therefore composed of those members of the population which remained after a 5-fold cumulative screening for the character in question.

Of such a group, mating was between 10 males and 10 females, all virgin, and approximately 4 days old.

Testing of the characteristics of the offspring was carried out in the same apparatus. 50 males and 50 females, in groups of 10 and approximately 2 days old were placed in *P*, and the number remaining in *P* after 2 min was counted. The summed scores are represented as percentage of the population showing aversion (percentage of flies which had passed beyond *D* in 2 min).

The results of artificial selection alone, natural selection alone, and the two in combination are shown in Figs. 2 and 3.

AN tends to show an overall rise over 14 generations. *NAN* shows a slight continuous upward drift. *UN* retains its original level, representing the relatively stable characteristics of the wild-type population. None of these results is particularly striking. The effects of artificial selection alone do not appear violent.

The behaviour of the graph *UP* does not seem to suggest that natural selection alone has much effect:

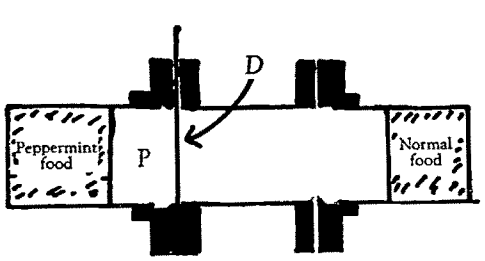

Fig. 1. Longitudinal section through testing and screening apparatus

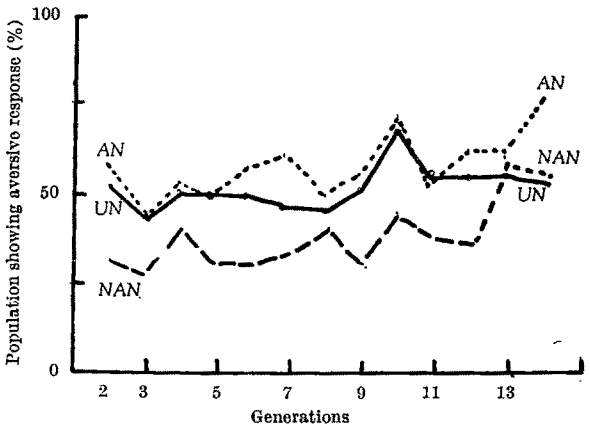

Fig. 2. Percentage of the population showing aversion at each generation. Flies reared on normal food

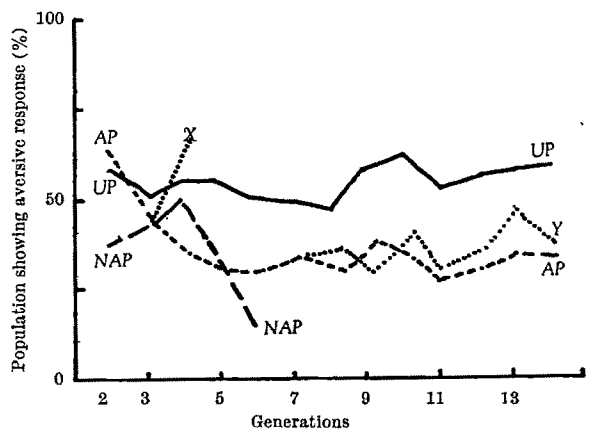

Fig. 3. Percentage of the population showing aversion at each generation. Flies reared on peppermint food

this line remains relatively stable over 14 generations at a level slightly below *UN*.

For the two lines which were subjected both to artificial and natural selection, however, the results are striking. *AP* and *NAP* both become non-aversive, though selected artificially in opposite senses. This result is not surprising for *NAP*. The data are only plotted up to F_6 since beyond this point the line had to be released from artificial selection owing to the very small numbers surviving. It appears to be extremely unfit, and afterwards had to be frequently released from artificial selection to maintain it. Beyond F_6 therefore the data for *NAP* are not reliable.

The most interesting line is *AP*. This line was selected for aversion in each generation, but becomes non-aversive when reared for several generations (approximately the same number over which Clutterbuck and Beardmore observed the effect) on peppermint. Neither artificial selection alone nor natural selection alone produced this effect (*NAN* and *UP*).

A point should be made about the method of testing. The method used means that the aversive response is partly confounded by the activity level of the flies. More active flies are more likely (other things being equal) to go beyond *D* in 2 min than less active flies. But since testing procedure was identical for all the lines the result is not artefactual and due simply to differences in activity-level in the original population. If the effect is due to activity rather than aversion, then we have altered activity by the experimental conditions. But one or other or both has been altered, which is what we are interested in.

A possible explanation might proceed along the following lines. Two processes seem to be occurring at once. If we release line *AP* from the adulterated medium at F_3 (shown by the dotted line in Fig. 3), it returns to its original

level of aversion (point X in Fig. 3). If, however, we wait until F_7 to release them, the progeny do not return to their original level (dotted line ending in point Y in Fig. 3). Moreover, the $AP(Y)$ line does not return to its original level even after a further 8 generations. The aversive character of the flies seems to have been reduced more or less permanently.

We suggest that the short-term effect should be called habituation, and that it is probably a within-one-generation effect. It seems not unlikely that flies which have spent their whole life from egg to adult in a peppermint-scented medium should habituate to it so that when tested as adults they would not be so aversive to it as wild-type flies tested when adults. On the other hand, the relatively stable, long-term effect bears a similarity, we would tentatively suggest, to genetic assimilation of a character which does not have a threshold, as was discussed for structural characters by Waddington[2]. If so, we may proceed with the explanation as follows.

Consider Fig. 4. A 5-fold screening is a rather intensive method of artificial selection, which may be expected to select only the extreme tails of the distribution marked A and NA respectively. In the total population there is a great deal of genetic variability, but comparatively little in the extremes of the distribution. Let us assume that the effect of the adulterated environment is to produce 'canalization' as described by Waddington. Then for the total population, the effect of canalization may well be small in each generation compared with the spread of genetic variability, so that the range of the latter offsets the effect of the former in such a degree that the overall characteristics of the population do not change noticeably. When we select for non-aversion and breed on peppermint (NAP) the two effects reinforce each other and the fall in aversion is precipitous and carries the population into a region where it is unfit; and in the case where we select for aversion but breed on peppermint, the following might occur. The variability is so reduced by the severe artificial selection that the effect of canalization is large with respect to it. Hence, although the artificial selection is in the opposite sense, the shift produced by canalization is not offset by the inherent variability, and the characteristics of the population slowly shift. What variability there is, however, tends to return the population toward the normal population, and so the line does not enter the unfit region which NAP enters, and instead, becomes stabilized at a comparatively low level of aversion.

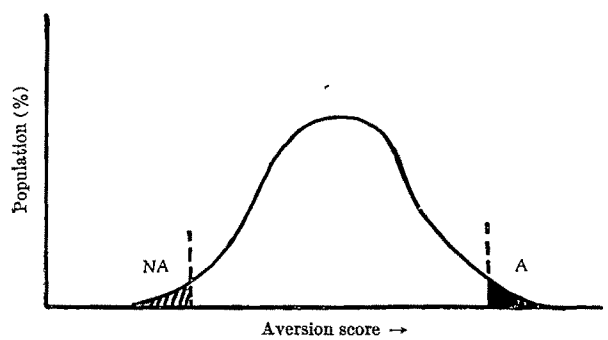

Fig. 4. Regions of population from which breeding is occurring on the basis of 5-fold screening selection

Such an explanation is amenable to experimental verification. It should follow that the rate of change of the characteristics of the population should be a function of the amount of variability in the breeding population. Thus by breeding from more or fewer pairs of flies a series of differently sloping curves should be obtained, all tending, but at a different rate, towards the non-aversive end of the distribution. We have begun experiments on this hypothesis, using an improved form of testing procedure.

We thank the Medical Research Council for financial assistance which made the work possible through the tenure of a research assistantship by one of us (K. C.) at the University of Sheffield.

CARBON DIOXIDE: A FACTOR INFLUENCING CELL DIVISION

By Dr. C. L. MER and D. R. CAUSTON
Agricultural Research Council Unit of Plant Physiology, Imperial College of Science and Technology, London, S.W.7

A HIGH concentration of carbon dioxide promotes mesocotyl growth in etiolated oat seedlings and reduces that of the coleoptile and leaves[1-4]. To explain these growth variations it has been supposed that carbon dioxide promotes cell division in the mesocotyl rather than the content of growth hormone[5]. This speculative hypothesis has now been tested by conducting a 2 × 2 factorially arranged experiment in which 5 per cent carbon dioxide in the air, for 3 days from the time of planting the seed, was combined with exposure of the seedlings to dim red light (1 ft.-candle) for 5 min on the third day, after treatment with carbon dioxide had been terminated. From the second to the seventh day of growth, samples of seedlings were measured and a plant having lengths nearest to the mean values obtained was selected from each sample, embedded in the usual way (either whole or after cutting into a series of 10-mm segments) and sectioned. Cell sizes and numbers were recorded for each mm of the entire length of both mesocotyls and coleoptiles by counting 5 rows of cortical cells and then calculating the mean cell length from the mean number of cells/mm. Fig. 1, which is self-explanatory, shows a typical set of data for a 10-mm segment of mesocotyl.

In Figs. 2*A* and *B* appear respectively the mean lengths of the mesocotyls plotted against time, and the mean

number of cells in a single column of the mesocotyl of a plant of average size. Length and cell numbers are clearly affected similarly by the treatments. The number of cells in the mesocotyls of untreated plants reached a maximum by the fourth day and afterwards remained more or less constant (Fig. 2*B*, solid circles). The mean mesocotyl lengths (Fig. 2*A*, solid circles) increased rapidly to the fourth day while cell division was proceeding; thereafter growth almost ceased. Since no further new cells were formed, this slight increase was due to the elongation of the cells which were immature on the fourth day. Carbon dioxide (Fig. 2*A*, solid squares) reduced mesocotyl growth up to the third day but the rapid elongation afterwards shown resulted in a greater final length. This elongation can be associated with rapid cell division beginning after the second day (Fig. 2*B*, solid squares) so that more cells were present on the third day, and mitoses continued until about the fifth day when the maximum number was reached. After exposure to light (Fig. 2*A*, open circles) the mesocotyls increased only slowly in length and they were finally some 25 mm shorter than untreated mesocotyls; cell division was inhibited (Fig. 2*B*, open circles). When both treatments were given (Fig. 2*A*, open squares) some capacity to elongate was retained and the final length was mid-way between that of untreated mesocotyls and those which had only been illuminated. Pre-treatment with carbon dioxide did not protect the meristem from the inhibitory effect of light (Fig. 2*B*, open squares). The cell numbers of the sixth and seventh days' samples were much lower than in the earlier ones, but at least they confirm that mitosis had ceased.

The distribution of cell size along the length of the mesocotyl on the fourth (*A* and *B*) and seventh (*C* and *D*) days is displayed in Fig. 3. In plants of all treatments the cells at the base of the mesocotyl were 0·2–0·3 mm long. With increasing distance from the base the cells rapidly attained a mature length with a mean value of 0·5 mm. In plants grown completely in darkness, cells of this size occupied most of the length of the mesocotyl. Near the coleoptilar node, in the case of the untreated plants on the fourth day (Fig. 3*A*) cell-length decreased rapidly over a distance of 5 mm to a minimum of 0·066 mm, whereas in the carbon dioxide treated plants a size of 0·043 mm was reached over a distance of 10 mm (Fig. 3*B*). These two features—more and smaller immature cells—support the observation (Fig. 2*B*, solid squares) that carbon dioxide maintained meristematic activity.

At the time of illumination none of the cells in the mesocotyl was mature. The tissue consequently comprised a sequence of cells, of increasing maturity from apex to base, whose capacity for elongation after return to darkness was determined by age at time of exposure. Thus, cells near the endosperm greater than about 0·13 mm were unaffected by light and elongated as much by the fourth day as the cells in the non-illuminated plants. Cells smaller than this, farther from the base, did not elongate as much as the cells in the corresponding positions of mesocotyls which had not been illuminated (Fig. 3*A*, compare open triangles and solid circles between 30 and 40 mm). The same is true for plants treated with carbon dioxide (Fig. 3*B*, between 20 and 35 mm). The cessation of cell division after illumination is indicated by the size of the topmost cells in the exposed mesocotyls as compared with those which remained in darkness; 0·13 mm and 0·066 mm in Fig. 3*A*, and 0·09 mm and 0·043 mm in Fig. 3*B*—approximately twice as long in both instances.

The measurements for the seventh-day samples (Fig. 3*C* and *D*) show that in darkness carbon dioxide did not affect the mean length which the cells finally attained (solid circles). Also, by this time most of the smallest

which remain small occur at the junction of the curved and straight parts of the mesocotyl (Fig. 4).

Growth of the coleoptiles is depicted in Fig. 5*A*; carbon dioxide depressed growth while exposure to light induced a transient growth promotion whether or no the plants had been given carbon dioxide. These treatment differences cannot be explained by effects on mitosis since cell numbers were not greatly influenced (Fig. 5*B*). However, coleoptile-length and mean cell-size are almost exactly correlated (Fig. 5, *A* and *C*). There are therefore two fundamental differences in the responses of mesocotyl and coleoptile cells to these treatments. First, coleoptile cells are changed in length by the different treatments whereas it is primarily cell division that is affected in the mesocotyl, and secondly, light promotes cell elongation in the coleoptile and depresses it in the mesocotyl. The only suggestion which can at present be advanced to account for the different effects of carbon dioxide on cell division in the mesocotyl and coleoptile is that it will influence mitosis only in a compact meristem such as that found at the node of the mesocotyl. In the coleoptile there is no clearly delimited meristematic region but individual mitoses occur sporadically throughout this structure.

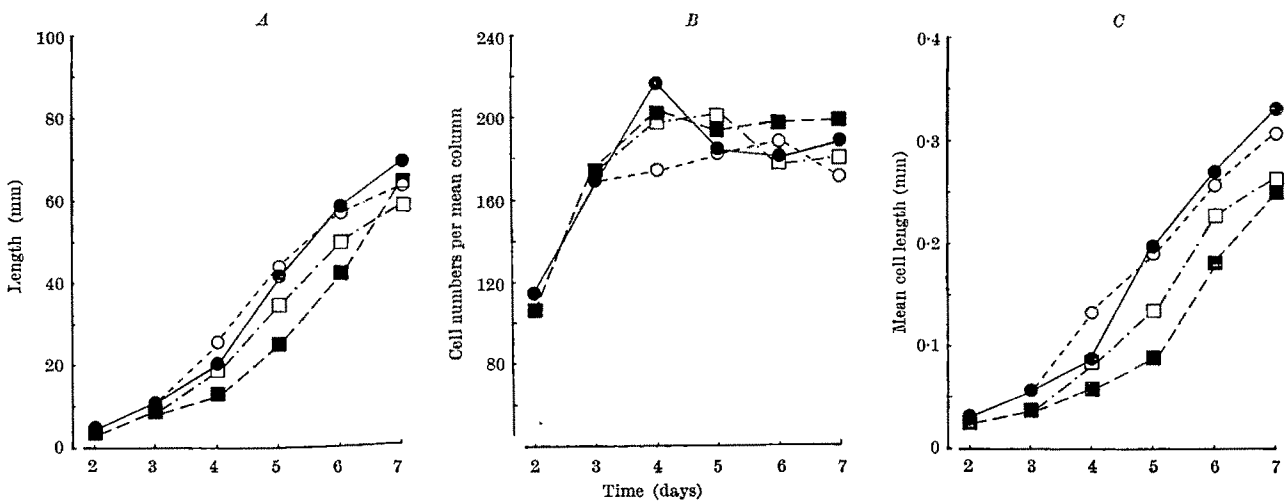

Fig. 5. The influence of carbon dioxide and light on length (*A*), cell numbers (*B*), and cell size (*C*) of the coleoptile on successive days □, Carbon dioxide and light; ■, carbon dioxide; ○, light; ●, untreated

cells in the mesocotyl had elongated further. Without carbon dioxide, the final length of the uppermost cells in the illuminated plants was slightly less than the mean value of 0·5 mm reached by the cells in the unexposed mesocotyls (Fig. 3*C*). In the plants treated with carbon dioxide (Fig. 3*D*) the topmost cells were equal in length, (between 30 and 50 mm). Situated between 35 and 40 mm (Fig. 3*C*) and between 15–20 mm (Fig. 3*D*) from the base, there appeared groups of short cells which apparently were so very sensitive to dim red light that only slight further growth was possible, to about 0·26 mm.

The growth and appearance of the mesocotyls of illuminated plants can now be accounted for in terms of cell division and elongation. The low growth rate of the mesocotyls (Fig. 2*A*, open circles between third and fourth days) can be ascribed to the cessation of mitosis and the inhibition of further elongation of some of the cells. The appearance of the plants on the fourth day is shown in Fig. 4; the white line indicates the position of the node. The lower part of the mesocotyl is characteristically curved and so it appears in the subsequent daily samples. This region contains the cells whose ability to elongate was unaffected by light. The short straight part includes the cells which did not elongate quite so much; the capacity for growth retained by the plants treated with carbon dioxide (Fig. 2*A*, open squares) is due to the large number of cells in this region which can elongate fully (Fig. 3*D*, open triangles). In both instances the cells

Two conditions thus seem to be required for the maintenance of cell division in the meristem: a high concentration of carbon dioxide and darkness. These circumstances normally prevail because the apical meristem and encircling leaves are enclosed within the coleoptile, and respiratory carbon dioxide will consequently be accumulated therein to keep the internal concentration at a high level. The nodal meristem is immediately proximal to the main apex and this group of small, tightly compacted cells will be bathed in respiratory carbon dioxide. In daylight the development of chlorophyll will screen the apical growing point from the inhibitory red radiation, but the nodal meristem is bare, contains no chlorophyll, and so is quite unprotected.

Recently, Sorokin reported that carbon dioxide at a concentration as low as 1 per cent inhibited cell division in *Chlorella*[6]. On this observation was based the suggestion that in multicellular organisms accumulation of carbon dioxide might inhibit mitosis and so could function as a controller of cell division. The present findings show that such a generalization is not possible since in the oat plant stimulation of cell division by carbon dioxide occurs in the meristem of the mesocotyl while the 'diffuse' mitoses occurring in the coleoptile are unaffected.

LETTERS TO THE EDITOR

ASTROPHYSICS

Solar Flux Fluctuations at 225 Mc/s and Noise-level of Atmospherics at 27 Kc/s

THE correlation between the behaviour of the ionosphere and solar activity has been investigated by many authors[1]. Nevertheless this research is being continued especially in connexion with the undisturbed D layer.

For this purpose the Wolf relative number R is usually considered as an index of solar activity, and the absorption of the D layer during the processes of ionospheric reflexion as an index of the ionospheric effect[2,3]. In our work, two different parameters have been used instead: the level of the solar flux at metric wave-lengths and the average noise-level of atmospherics at very low frequency. Thus we have compared the average antenna temperature at 225 Mc/s produced by the Sun during its meridian transit (excluding bursts) and the median of the hourly values of atmospheric noise recorded at 27 kc/s.

Both values were recorded at the same place (Arcetri Observatory): the solar results expressed in deg. K were obtained with a two-element (Yagi) interferometer spaced at 38 wave-lengths; the atmospheric results were obtained from a conventional receiver (passband 0·500 kc/s) fed by a loop antenna and are expressed in μV/m.

Our recordings cover the period June 1–November 30, 1962, with one gap of 10 days: Fig. 1 shows the values of the solar flux at noon (F) compared with the median of the hourly values of atmospheric noise obtained during the day (D) and separately during the night (N). It appears that maxima of F almost always coincide with maxima of atmospheric noise. The agreement is more evident for the nightly values N. The vice versa is not true possibly because of rather near and concentrated atmospheric sources.

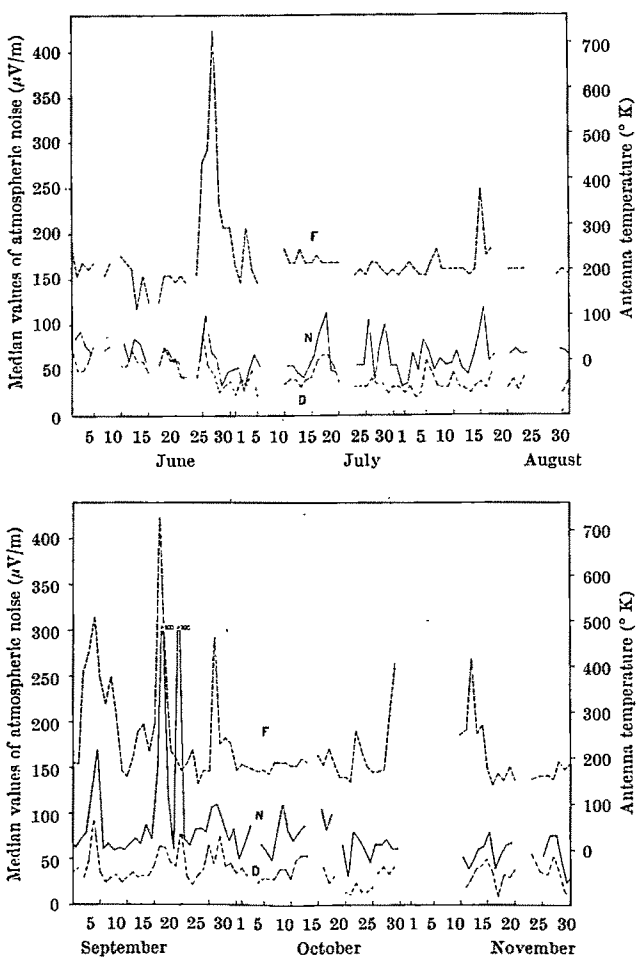

Fig. 1. Daily values of the solar flux at 225 Mc/s (F) at noon. Daily median intensity of atmospheric radio noise at 27 kc/s during the days (D) and the nights (N)

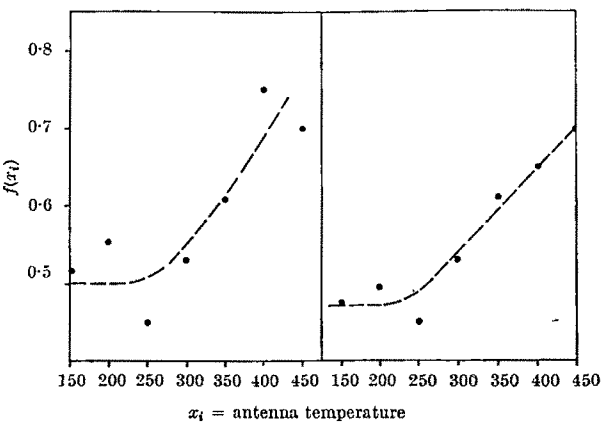

Fig. 2. $f(x_i)$ for the day (left) and for the night (right)

We then computed the correlation coefficients between F and D (same day) and between F and N (following night); the results are not very significant.

Considering the large number of parameters conditioning the atmospheric noise, the low value of these coefficients are not surprising; so we looked for a correlation restricted only to those days in which the solar flux was reaching a certain level.

Since our values for the antenna temperature are at a minimum of about 150° K we counted the coincidences between the F values higher than 150° K and the D and N values higher than their monthly median value.

With $N(x_i)$ as the number of the F values higher than the threshold x_i and $n(x_i)$ the number of the observed coincidences, we computed the ratio:

$$f(x_i) = n(x_i)/N(x_i)$$

for values of x_i increasing from 150° K to 450° K, 50° K by 50° K. If the coincidences are at random, $f(x)$ must be obviously 0·5.

The graphs of Fig. 2 show the behaviour of $f(x)$, as a function of x. It is interesting that increases of $f(x_i)$ occur for the nightly values as well as for the daily ones.

In order to check this result we repeated the same experiment comparing F with the value of D of the following day: no matter what the x_i value was, $f(x_i)$ was statistically ranging around 0·5 and not increased at all with the value of x_i.

We have again repeated the foregoing calculus associating D and N with the daily Wolf number (R), given by the Freiburg[4] maps.

As for F (Fig. 2), also for the Wolf numbers we have found a threshold ($R \simeq 40$) beyond which an increase, though weaker, of $f(R_i)$ with R_i can be seen.

We may therefore say that: (1) The correlation between the solar flux and the atmospheric noise-level refers to the same day and the following night. (2) There seems to be no relation between the two phenomena when $F < 250°$ K; our average antenna temperature for quiet Sun is around 200° K. It will be noted that Nicolet and Aikin[5] in

1960 found by theoretical consideration the existence of a 'threshold' of this kind in the *D*-region ionization.

GEOPHYSICS

Terrestrial Heat Flow in Japan

Since 1957 a survey of terrestrial heat flow has been conducted in Japan by this Institute[1,2]. As a result of this, heat-flow values have so far been determined at 39 localities in the Japanese Islands. In addition to these, 12 sea measurements have been made in the sea around Japan under a co-operative programme with the Japan Meteorological Agency on board the R.V. *Ryofu Maru*[3]. The results (Fig. 1) seem to indicate a definite pattern of heat-flow distribution in the area.

Estimation of heat flux has been made from combination of the geothermal gradient and the thermal conductivity of rocks in which the thermal gradient was measured. Of the total of 39 land stations, 26 are metal mines, 4 coal mines, 2 oil fields, 3 natural gas fields, 1 railway tunnel, and 3 are sites of other types (Fig. 1).

The geothermal gradient was obtained from measurement in deep boreholes or in short boreholes at various levels in mines. At most of the land stations, the maximum depth of temperature measurement exceeded 300 m. At 24 stations, it was more than 500 m. Thermal conductivity of rocks was measured by the divided-bar method[4]. The apparatus was calibrated with such standard substances as fused silica, crystalline quartz, dense flint glass and borosilicate crown glass, of which thermal conductivities were determined by E. H. Ratcliffe of the National Physical Laboratory, England[5].

Geothermal gradient in the sea bottom has been obtained by a thermogradmeter developed by us[6], and the thermal conductivity of sediments recovered from the bottom was measured either by the divided-bar method or the needle-probe method[7].

Errors accompanying the heat-flow values were estimated from the probable error in the thermal gradient and the degree of ambiguity in assessing the *in situ* thermal conductivity of the strata from the thermal conductivities of individual samples. In most cases, the amount of the errors is about 10 per cent.

As can be seen in Fig. 1, there were two measurements which gave very high heat flow, that is, one at Toyoha Mine in south-western Hokkaido ($> 5 \times 10^{-6}$ cal/cm² sec) and the other at Mt. Kusatsu-Shirane ($10{\cdot}8 \times 10^{-6}$ cal/cm² sec). Both of these high values were found to be due to very local geothermal anomalies. Excluding these two anomalous values, the average value of the 37 heat-flow values on land turns out to be $1{\cdot}55 \times 10^{-6}$ cal/cm² sec, and the average of the 12 sea values $1{\cdot}48 \times 10^{-6}$ cal/cm² sec. Since the land stations are distributed fairly uniformly over the Japanese Islands, the foregoing figure may be regarded as the representative heat flux of the whole area. This value is not much different from the average continental heat flux ($1{\cdot}2$–$1{\cdot}4 \times 10^{-6}$ cal/cm² sec). However, the distribution of heat flow indicated in Fig. 1 seems to have some features which are possibly characteristic of the thermal state in the crust and the upper mantle of an Island arc orogenic zone.

The features to be noted may be as follows. (1) There exists a region of high heat flow on the inner side of the Japanese arc, where the heat flow value exceeds $2{\cdot}00 \times 10^{-6}$ cal/cm² sec. There are indications that the high heat-flow region branches off southward in the central part of the Honshu Island along the Fossa Magna. This may extend farther south to the Izu-Mariana arc. High value ($2{\cdot}54 \times 10^{-6}$ cal/cm² sec) at Konomai in north-eastern Hokkaido may be an indication of existence of similar high heat flow zone in the Kuril arc. It should be noted that these high heat-flow regions coincided with those of Cainozoic volcanic activity of the area[8,9]. Although there are some high heat flow values in the Pacific, the data are still too meagre to define any area of high heat flow. (2) A region of low heat flow ($< 1{\cdot}00 \times 10^{-6}$ cal/cm² sec) exists on the Pacific Ocean side of the north-eastern Honshu. This tendency is confirmed by a sea measurement ($0{\cdot}27 \times 10^{-6}$ cal/cm² sec). As marked by an oval with cross-hatches this low heat-flow area seems to be bounded in the east by the Japan Trench. Although measurements are too few to draw any general conclusion, the bottom of the trench itself so far showed rather normal heat flow ($1{\cdot}14$ and $1{\cdot}39 \times 10^{-6}$ cal/cm² sec).

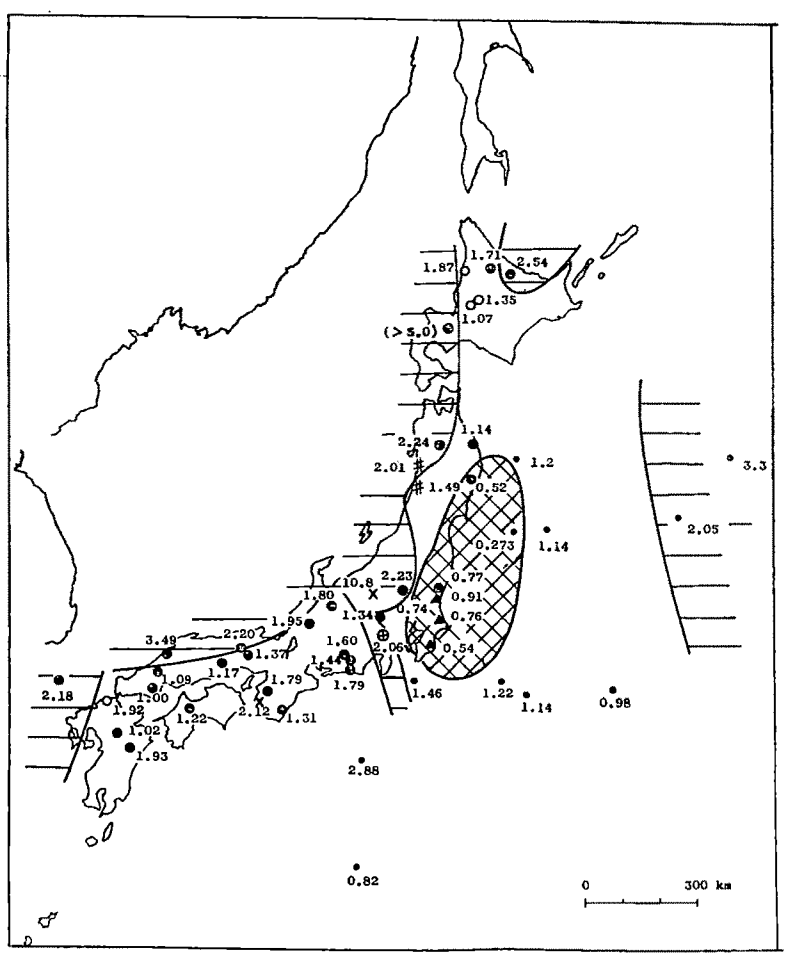

Fig. 1. Distribution of heat flow in and around Japan. Unit: 10^{-6} cal/cm² sec. ●, metal mine; ○, coal mine; #, oil field; ▲, gas field; ⊕, railway tunnel; ×, other type; •, sea station. One sea station out of the map is omitted

(3) With the exception of measurements in these two regions, almost all the land heat flow values are between 1 and 2×10^{-6} cal/cm² sec. The zones of intense Mesozoic orogeny in Japan occupy most of these non-high heat-flow regions[10].

Obviously the distribution of the heat flow obtained here should be examined in relation to many other geological and geophysical factors of the Japanese Islands and their environment. Description of each heat flow station[2] and some discussion on the results will be published elsewhere.

We thank Prof. T. Rikitake of the Earthquake Research Institute and many people at heat-flow stations for their assistance.

Reverse and Normal Remanent Magnetization in Hydrothermal Veins

AN attempt has been made to apply the measurements of the direction of natural remanent magnetization to the age determinations of epigenetic hydrothermal mineralization. The investigation of materials from Czechoslovakian hydrothermal deposits has brought positive results which have changed some of the previous opinions concerning metallogenetic problems in Czechoslovakia[1]. The work was based on several scores of hydrothermal deposits from four metallogenic areas in the West Carpathians and in the Czech Massif. As a comparative geochronological scale for age-determinations the polar wandering curve computed in the way published by Creer *et al.*[2] was used. In the hydrothermal mineral deposits of the Carpathian System the parameters introduced by Blackett *et al.*[3], particularly the so-called divergence and inclination difference of remanent magnetization, were also used.

The fundamental condition for a correct age interpretation of the products of hydrothermal mineralization is that they reproduce the primary direction of the remanent magnetization. It is thus necessary to eliminate the influence of post-mineralization tectonics[4] and to prove the magnetic stability of the hydrothermal aggregates under investigation. Stability in d.c. magnetic field (up to 56 œ) and especially in a.c. magnetic fields (up to 900 œ) was shown by various hydrothermal minerals, for example, by baryte, fluorite, magnesite, quartz, calcite, which were finely pigmented by hæmatite. A high stability and homogeneous magnetization distinguished the so-called cinopels, hæmatite–quartz aggregates, where hæmatite occurs in a fine dispersed form isolated in a quartz ground-mass.

Laboratory stability tests cannot yet serve as a proof of palæomagnetic stability, especially with products of hydrothermal mineralizations where influence of later hydrothermal processes may occur. I have endeavoured to find in each metallogenic area hydrothermal aggregates with normal and with reverse magnetization differing within the limits of the confidence circles by 180°. Such aggregates have been found in three metallogenic areas, both in the West Carpathians within the same general hydrothermal mineralization, in the Czech Massif, and finally in the Krušné Hory (*Erzgebirge*) in the *Geschieber* vein.

The last case is the most interesting one from the geophysical point of view. In Jáchymov the *Geschieber* vein is developed with a vertically banded structure. The outer bands are constituted by cinopels which are penetrated by a vein of earthy hæmatite. The individual

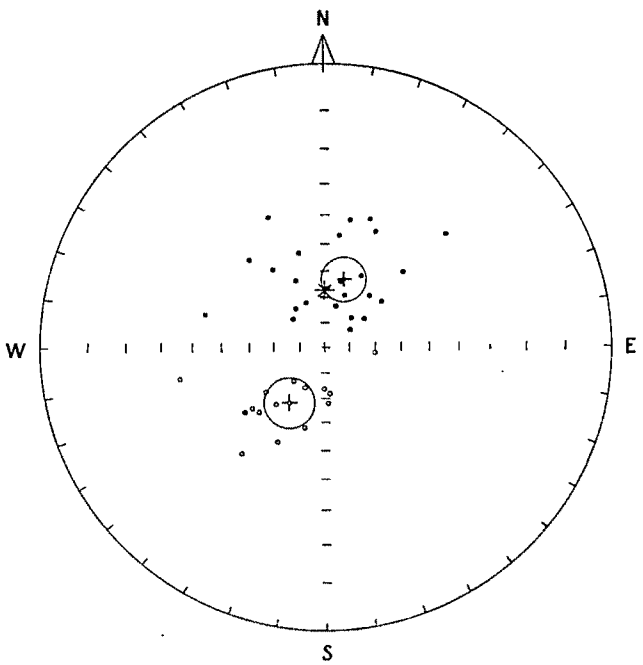

Fig. 1. Stereographic projection of the vectors of palæomagnetically stable remanent magnetization from the *Geschieber* vein, mine 'Svornost', locality Jáchymov, Krušné Hory region, Czechoslovakia. The full circle denotes the projection of the magnetization vector into the lower hemisphere; the empty circle denotes the projection into the upper hemisphere. Around the mean directions marked by a cross traversing a full or an empty circle are drawn the confidence circles. The asterisk marks the direction of the present-day theoretical dipole field

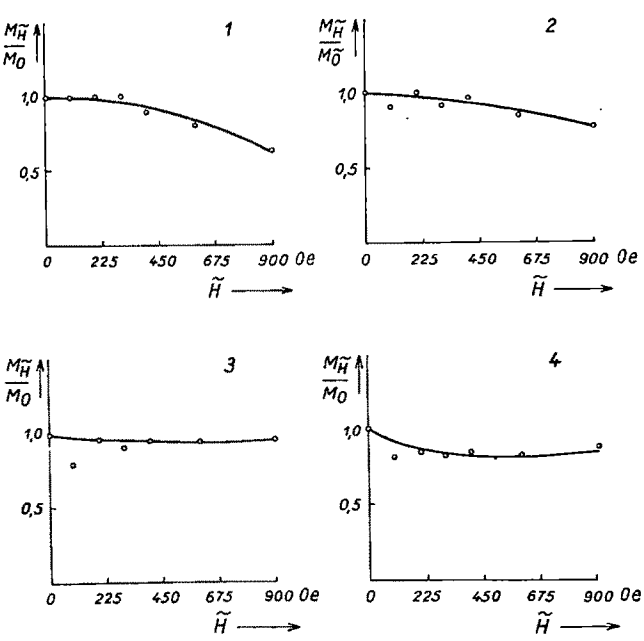

Fig. 2. A.c. demagnetization of samples from the *Geschieber* vein, in Jáchymov. The symbol $M_{\tilde{H}}$ indicates the magnitude of magnetic moment of sample demagnetized by field $\tilde{H}$ and the symbol M_0 magnetic moment of non-demagnetized sample

Table 1. Mean Directions of Remanent Magnetization of Nine Normally (Nor) and of Nine Reversely (Rev) Magnetized Samples

Peak value of a.c. demagnetizing field (œ)	Declination (deg.)		Inclination (deg.)		α (deg.)		k		R	
	Nor	Rev	Nor	Rev	Nor	Rev	Nor	Rev	Nor	Rev
0	17	205	64	−66	10·5	12	24·24	19·51	8·67	8·59
200	17	206	65	−66	10·5	11·5	25·81	21·05	8·69	8·62
400	18	208	64	−67	10·5	12	25·81	19·05	8·69	8·58
600	18	212	65	−64	10·5	14	25·00	15·09	8·68	8·47

veinlets (bands) evidently represent products of different mineralization acts belonging to the same general hydrothermal mineralization. The veinlet of earthy hæmatite showed reverse remanent magnetization with respect to the normal magnetization of the cinopels (Fig. 1). Nine normally and nine reversely magnetized samples were separated from the collection and subjected to the demagnetization in alternating magnetic field. The tests proved a high stability of samples in the alternating field, as it is seen that data given in Table 1 (Fig. 2) illustrate demagnetization graphs of four representative samples, of normally[1,2] and oppositely[3,4] magnetized ones. The foregoing phenomenon indicates that products of different mineralization acts belonging to different periods of one and the same general hydrothermal mineralization reveal remanent magnetizations differing mutually by 180° in their directions. This phenomenon is analogous to that which has been found many times in lavas and sediments, and which in the majority of cases has been interpreted as being due to the reversal of the geomagnetic field in the geological past.

The *Geschieber* vein was formerly considered by most authors to be of Permian age, but the palæomagnetic examinations suggest the Neoid (most probably the Tertiary) age of the hæmatite-containing assemblages in this vein. As it has been palæomagnetically found also in other deposits of the Krušné Hory region, much of the mineralization in this classical area is much later than generally thought.

PHYSICS

Cæsium-137 in Air and Precipitation in Norway during October 1957

In an earlier communication[1] we reported a relatively heavy deposition of cæsium-137 at Bergen, Norway, during the period September–October 1957. We suggested that this might have been due chiefly to the Windscale accident, meaning that about 5 mc./km² of the measured 7·4 could not easily be accounted for by nuclear weapons tests, as the deposition in neighbouring periods was about 2 mc./km² or less.

Booker and Chamberlain[2] found it unlikely that a cæsium-137 deposition of 7 mc./km² at Bergen, 800 km from Windscale, was due to the accident, considering that the 20 mc./km² isopleth lay at an average distance of about 30 km from Windscale. We wish to re-affirm our suggestion by presenting more results concerning radioactivity in air and precipitation in Norway.

Measurements of cæsium-137 in ground-level air carried out at the Norwegian Defence Research Establishment give the following mean values for October 1957:

Sola	(58·9° N., 5·6° E.)	0·039 pc./m³	
Bergen	(60·4° N., 5·4° E.)	0·016 ,,	
Finse	(60·6° N., 7·5° E.)	0·007 ,,	(1,200 m above sea-level)
Kjeller	(60·0° N., 11·1° E.)	0·017 ,,	(ashed filters)
Gardermoen	(60·2° N., 11·1° E.)	0·022 ,,	
Værnes	(63·5° N., 11·0° E.)	0·006 ,,	
Tromsö	(69·7° N., 19·0° E.)	0·004 ,,	
Vadsö	(70·1° N., 29·7° E.)	0·002 ,,	

The filters from Sola, Finse, Gardermoen, Værnes and Tromsö covering the period October 9–17 were also measured at the Atomic Energy Research Establishment, Harwell. The results were[3]:

All filters, October 9–15, iodine-131, nil.
Sola, October 15–16, iodine-131, 2·03 pc./m³, cæsium-137, 0·75 pc./m³.
Sola, October 16–17, iodine-131, 0·54 pc./m³ (cæsium-137 not given).
Gardermoen, October 15–16, iodine-131, nil.
Gardermoen, October 16–17, iodine-131, 0·66 pc./m³, cæsium-137, 0·23 pc./m³
Finse, Værnes, Tromsö, October 15–17, iodine-131, nil.

The cæsium-137 collected at Sola during October 15–16 accounts for 62 per cent of the mean value for October. The amount collected during October 16–17 accounts for another 17 per cent, using the same iodine-131 to cæsium-137 ratio.

The cæsium-137 collected at Gardermoen during October 16–17 accounts for 34 per cent of the mean value for October.

Apparently the fact cannot be excluded that the filters from Værnes and even Tromsö also contained significant amounts of iodine-131 and cæsium-137 during October 17–18 or 18–19.

The cæsium-137 activity in ground-level air at Chilton (51·5° N. 1° W.) has been reported by Peirson *et al.*[4]. The mean value for October 1957 is 0·0062 pc./kg, that is, 0·008 pc./m³. It is interesting to note that this is about 1/5 of the activity at Sola.

The deposition and activity of cæsium-137 in precipitation in Norway during October 1957 were:

Kjevik	(58·2° N., 8·1° E.)	1·1 mc./km²	10·6 pc./l.
Sola		2·1 ,,	9·5 ,,
Bergen		6·5 ,,	11·7 ,,
Finse		0·31 ,,	2·2 ,,
Kjeller		0·36 ,,	6·1 ,,
Gardermoen		0·56 ,,	7·6 ,,
Værnes		0·61 ,,	4·3 ,,
Bodö	(67·3° N., 14·4° E.)	0·97 ,,	3·2 ,,
Bardufoss	(69·1° N., 18·5° E.)	0·13 ,,	1·6 ,,
Tromsö		0·13 ,,	3·2 ,,
Vadsö		0·18 ,,	3·5 ,,

Of the 6·5 mc. cæsium-137/km² deposited at Bergen during October 1957, 5·0 mc./km², or 77 per cent, was deposited during the period October 13–27, corresponding to 21 pc./l. precipitation. 1·2 mc./km² was deposited during October 1–13 and 0·29 mc./km² during October 27–31.

The activity of cæsium-137 in precipitation at Milford Haven (51·5° N. 5° W.) and Chilton has also been reported by Peirson *et al.*[4]. The results for October are:

Chilton	5·2 pc./l. in 50 mm precipitation, that is, 0·26 mc./km²
Milford Haven	8·4 pc./l. in 149 mm precipitation, that is, 1·25 mc./km²

It appears that activity of cæsium-137 in precipitation and corresponding deposition was less at Milford Haven and Chilton than at Bergen.

A possible explanation is that the cæsium-137 deposited at Bergen came from nuclear weapons tests. However, the cæsium-137 to strontium-90 ratio makes this unlikely. The strontium-90 deposition at Bergen has been measured at the Division of Chemistry of this establishment[5]. The cæsium-137 to strontium-90 ratio is 18 for the period October 13–27. This is about 10 times higher than expected in fall-out from nuclear bombs, and suggests that up to 90 per cent or 4·5 mc./km² of the cæsium-137 deposition at Bergen during the period October 13–27 was due to the Windscale accident, the strontium-90 release at which has been given as less than 1 per cent of the cæsium-137 release[6]. The cæsium-137 to strontium-90 ratio is 1·7 for the period October 1–13 and 1·9 for the period October 27–31.

The weather situation in the area between Windscale and Norway, October 10–17, 1957, has been examined by Storebö[7]. The main feature during the first four days after

October 10 was a centre of high pressure moving from the west over England and spreading out over central Europe. At the same time small changes in the high caused backward and forward air movements over England and the North Sea. During the evening of October 14 a south-westerly wind field over England and the North Sea was initiated by a centre of low pressure moving towards the British Isles from the west. This wind field grew successively over the Scandinavian Peninsula and forced the lower air layers in the former high to move to north-north-east. Thus radioactivity from Windscale reached south-west Norway during October 15–16. In this weather situation, little rain fell while the cloud from Windscale passed over England[8]. In Norway, on the other hand, the passage of the cloud was accompanied by heavy rain in several places. It is concluded, therefore, that the meteorological conditions caused a heavier deposition of cæsium-137 from the accident at some places in Norway than at others closer to Windscale.

Some Effects of Electron Irradiation on the Young's Modulus of Graphite

Following detailed investigations[1,2] of the changes in the thermal and electrical properties of pure pile graphite after electron irradiation at liquid nitrogen temperature, a similar study has been made of changes in the Young's modulus of this material.

The specimens were in the form of rods 3 mm square and 50 mm long, and Young's modulus was measured using a cantilever technique with the specimen supported at both ends and the load applied at its centre. The central displacement was measured using a transducer.

A preliminary examination was made of the Young's modulus as a function of specimen temperature between 80° K and 400° K. It was found that Young's modulus increased as the temperature was lowered, but that both the magnitude and temperature dependence of this quantity varied from specimen to specimen. It has been pointed out by Simmons[3] that the elastic property involved is the sheer modulus of the crystallites.

The specimens were immersed in liquid nitrogen, and irradiated by 4 MeV electrons using a similar technique to that described for the earlier work[1,2]. The beam current incident on the specimen was 10–20 μamp, and irradiation periods of 1–8 h were used. The actual dose the sample received was monitored in terms of its electrical resistance, and changes of 3–37 per cent were recorded. During the irradiations and subsequent transfer to the measuring and annealing apparatus the specimen temperature was kept below 80° K. The annealing was carried out using the pulse technique described in the previous papers[1,2], that is, the specimen was heated rapidly to the annealing temperature, which was maintained for 1 min, and then rapidly cooled. The specimen temperature was measured by thermocouples inserted in it, and the Young's modulus measurements were all made at a standard temperature of 80° K.

In all the specimens measured there was no initial change in Young's modulus following the irradiation. On annealing, Young's modulus remained constant until a temperature of about 200° K had been reached. Above this temperature there was a sharp inverse annealing peak with a maximum about 270° K. Fig. 1 shows the Young's modulus as a function of annealing temperature for specimens which had different irradiation doses.

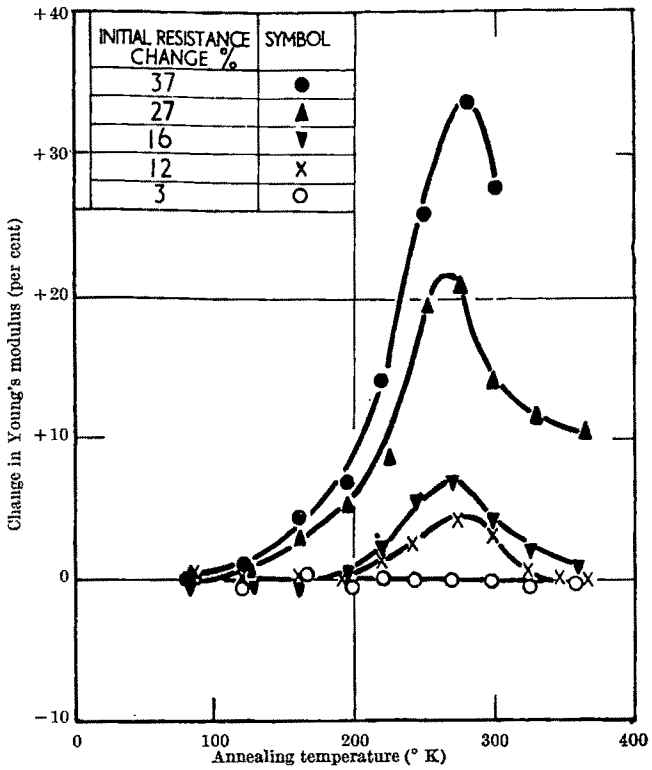

Fig. 1. Change in Young's modulus of graphite as a function of annealing temperature

The height of the peak is found to vary as the square of the initial resistance change. As the irradiation dose is increased the anomalous rise sets in at a lower temperature and the peak develops a plateau on the high-temperature side. It coincides exactly with the inverse annealing peak observed in the annealing of thermal resistivity.

Pile graphite is composed of small crystallites, and single interstitials are only mutually accessible if they lie between the same pair of basal planes in the same crystallite. Then for small numbers of mutually accessible interstitials the chance of di-interstitial formation increases as the square of the dose. Thus the anomalous Young's modulus peak may be associated with the formation of di-interstitials. The plateau seen in the higher dose specimens arises because of the greater probability of forming larger complex groups such as 4's as the dose is increased.

The fact that single interstitials cause no change in Young's modulus, and pairs have such a marked effect suggest that the linking bond of a di-interstitial may serve as a coupling between neighbouring basal planes. This implies that the explanation of the inverse annealing of thermal resistivity in terms of Rayleigh scattering may not be adequate and that it is the increased coupling between neighbouring planes on di-interstitial formation that is largely responsible.

Noting that the anomalous peak in Young's modulus is removed by annealing to 290° K and applying a 2-dimensional diffusion equation, we find that the activation energy of motion of a di-interstitial is 0·9 eV, in agreement with results given previously[2]. The build up of the peak is also consistent with the previously estimated value of 0·5 eV for the activation energy of motion of a single interstitial. It is not consistent with the lower values inferred more indirectly by Schweitzer[4], or those calculated purely theoretically by Iwata *et al.*[5].

The relative insensitivity of Young's modulus to single defects and its high sensitivity to complex groups makes it a useful property for the study of their formation in the graphite lattice.

Use of Complex Ions in the Efficiency Tracing Method for the Standardization of Pure Beta-emitting Nuclides

The absolute standardization of pure β-emitters by 4πβ-counting involves errors due to uncertainties in self-absorption. This difficulty may be overcome by the use of the efficiency-tracing technique described by Campion *et al.*[1]. The technique involves the inclusion of a suitable β-γ-emitting nuclide with the pure β-emitter in the deposited source and the use of β-γ-coincidence counting to determine the efficiency of detection of the betas arising from the β-γ or 'tracer' nuclide. Knowledge of the β-efficiency for the tracer in a series of sources may then be used to determine the absolute activity of the pure β-emitter.

Choice of a suitable tracer is limited by certain physical requirements. Ideally the spectral shapes of the tracer and the pure β-emitter should be identical. The β-end-point energies of the two nuclides should be close to one another. The decay scheme of the tracer should be simple, if possible with a single β-branch, and there should be little internal conversion.

Nuclides fulfilling the requirements for a simple decay scheme which also have maximum β-energies of less than 1 MeV are scandium-46, cobalt-60, bromine-82, niobium-95, cerium-141, lutecium-177, gold-198 and mercury-203.

The choice of a tracer is further restricted by certain chemical considerations. To ensure that the corrections are reliable it is essential that the tracer and the pure β-emitter are deposited uniformly throughout the volume of the source; any separation of the two nuclides will introduce errors. In practice, as ionic solutions are usually employed, the best results will be obtained with a tracer ion opposite in charge to the pure β-emitting ion. This encourages the formation of a deposit in which the two ions are evenly distributed, and in which, in favourable cases, they are incorporated in a common lattice as a clearly defined compound.

For the determination of anions such as $^{35}SO_4^{=}$ there is a wide choice of tracer cations, but for the measurement of cations the selection is very much more limited. Of the tracers mentioned here, only bromine-82 normally occurs as an anion. In order to rectify this position we suggest the use of anionic complexes of suitable nuclides as tracers for the measurement of pure β-emitting cations. Complexes of this kind can be readily formed by interaction of the cation and a suitable ligand. One such ligand is the cyanide ion, which will combine with cobalt, gold or mercury to give very stable anionic complexes.

Using a solution containing potassium cobalticyanide prepared in this way from a cobalt nitrate solution labelled with cobalt-60 we have applied the technique to the standardization of calcium-45 and promethium-147. Full details of these measurements will be published elsewhere.

There is no reason why the technique should be limited to cyanide complexes and it seems probable that suitable complexes can be prepared for each of the tracer nuclides listed above. Although the number of pure β-emitting cations which require tracer measurements of this kind is small, the wider choice of tracer offered by this technique should be of value in improving the accuracy of the standardizations.

CHEMISTRY

Energy of Formation of D-Defects in Ice

Much of the literature dealing with the dielectric properties of ice[1] has used Bjerrum's concepts of D- and L-defects[2]. A pair of D- and L-defects is formed (Fig. 1) when a water molecule in ice rotates through 120° around one of its O–H . . . O axes, thus leaving one pair of neighbour O . . . O atoms with no intervening hydrogen atom (L-defect), and another pair of neighbours O–H . . . H–O with two hydrogens (D-defect). A subsequent similar rotation of the appropriate molecule adjacent to the L-defect separates these two defects.

Recently, Dunitz[3] has suggested that the repulsive interaction of the two hydrogen atoms in a D-defect is so great that its formation is unlikely. He proposes an alternative to the D-defect, called an X-defect, in which repulsive interactions of hydrogens are reduced. We wish to point out that if changes in bond-lengths and -angles in the neighbourhood of a D-defect are considered, then the H . . . H repulsion energy in this defect will be considerably less than that calculated by Dunitz. These changes, which we shall refer to as a 'relaxation' of the lattice, occur with relative ease owing to the relatively weak bonding in the neighbouring H . . . O bonds.

If no relaxation occurs in a D-defect, then the two hydrogen atoms are at a separation of 0·78 Å (O_1-H_1 . . . H_2-O_2, Fig. 2). We have confirmed the result of Dunitz that their repulsive interaction energy in this case is about 60 kcal mole^{-1}.

Let us now allow relaxation to occur: O_1 moves a distance Δr to O'_1, and O_2 a similar distance in the opposite direction to O'_2. In addition the length of the bond O_1-H_1 is compressed from a to a''. If we assume that O_3 is fixed, then the O_3-H_3 . . . O_1 angle is reduced

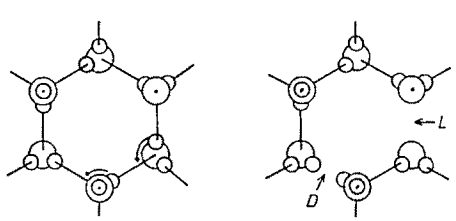

Fig. 1. Formation of a pair of D- and L-defects in ice

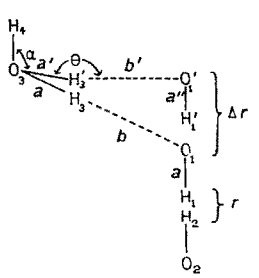

Fig. 2. Changes in bond-lengths and -angles in the neighbourhood of a D-defect shown schematically. The actual lengths and angles are given in the text

from 180° to θ, and the $H_4-O_3-H_3$ angle from 109·47° to α. The $O_3-H_3\ldots O_1$ distance is reduced from $(a+b)$, which is 2·76 Å, to $(a'+b')$.

Similar relaxations occur in the other adjacent molecules.

We now seek the values of a', a'', b', θ, α which minimize the total energy. This total energy comprises $H'_1\ldots H'_2$ repulsion, twice the $H'_1-O'_1$ compression energy, and six times the various $H_4-O_3-H'_3\ldots O'_1$ bending and compression energies. For the H . . . H repulsion we have used Hendrickson's semi-empirical[4] potential:

$$V(r)=10{,}000\ \exp(-4{\cdot}6r)-49{\cdot}2r^{-6}$$

where V is in kcal mole^{-1} and r is in Å. The other force constants are taken to be[6]: k(O−H compression) = 8·07 derived from spectroscopic data (ref. 5), $k(O_3-H_3\ldots O_1$ compression) = 0·155, $k(O_3-H_3\ldots O_1$ bending) = 0·085, $k(H_4-O_3-H_3$ bending) = 0·56, all in units of 10^5 dynes cm^{-1}. The resulting minimum energy is 5·19 kcal per mole of D-defect, and it occurs when $r=1{\cdot}80$ Å, $\Delta r=0{\cdot}50$ Å, $a-a''=0{\cdot}01$ Å, $a'=0{\cdot}99$ Å, $b'=1{\cdot}66$ Å, $\theta=169{\cdot}75°$, $\alpha=105{\cdot}47°$. If we now also allow O_3 and the five other first-neighbour oxygen atoms to O_1 and O_2 to relax, this energy will be even lower.

Since relaxation has the effect of reducing the sum of the repulsive and strain energies in a D-defect from about 60 kcal to about 5 kcal it is clear that the existence of such defects cannot be ruled out.

A more detailed comparison of the total energies of formation of D- and X-defects is being prepared.

We thank Mr. C. W. Haigh for helpful discussions.

Decomposition of Alkali Metal Nitrates by Light Ions of Kilovolt Energy

When alkali metal nitrates are bombarded by positive ions of energy in the range 1–15 keV a decomposition occurs, the main features of which are represented by the stoichiometric equation:

$$NO_3^- \rightarrow NO_2^- + \tfrac{1}{2}O_2 \qquad (1)$$

Using a fairly uniform ion beam the yield of nitrite, y, is related to the dose, x, by the equation:

$$y=y_s(1-e^{-bx}) \qquad (2)$$

where y_s is the saturation yield and depends on the alkali metal and b is a constant. This is shown in Fig. 1 for the nitrates of potassium and rubidium using the narrow beam (½ in. diam.) and may be deduced for the others since the yields produced by a non-uniform beam are a constant fraction of those from potassium nitrate when a similar dose is given, as shown in Table 1. D^+ ions of 2 keV were used in these experiments and from the initial slopes $G(NO_2^-)$ may be calculated as 0·6, 1·8, 2·0, 1·5 and 1·4 for the nitrates of lithium, sodium, potassium, rubidium and cæsium. At both high and low temperatures there are observed increases in yield, which follow different types of dependence on dose, as shown in Fig. 2.

In a recent paper[1], a model for this decomposition was used which (it seems to me) is inadequate in certain important respects, and the purpose of this communication is to present an alternative interpretation of the reaction processes which is qualitatively consistent with the

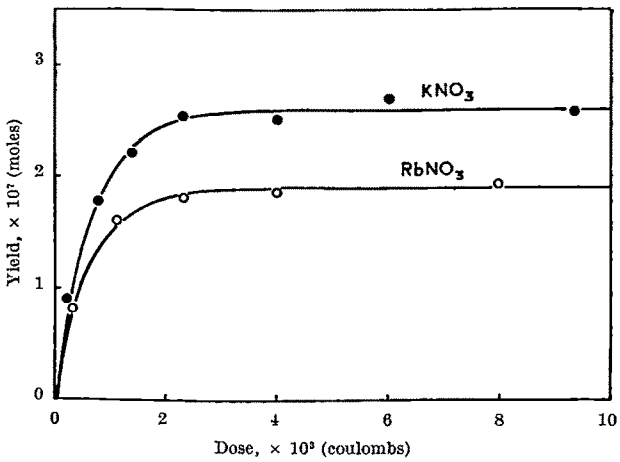

Fig. 1. Nitrite yield from potassium nitrate (●) and rubidium nitrate (○) as a function of the dose of 2 keV D^+ ions

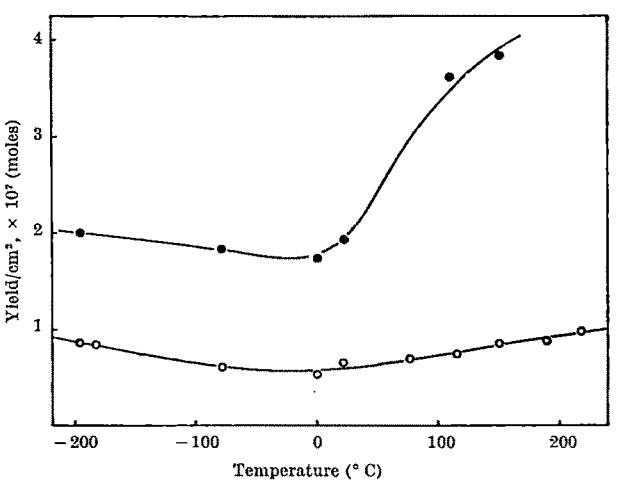

Fig. 2. Variation with temperature of the yields of nitrite/cm² at doses of 0·23 × 10^{-3} (○) and 3·0 × 10^{-3} (●) coulombs/cm² of 2 keV D^+ ions

experimental results and with revised assessments of the displacements produced by atomic collisions.

From equation (2) the increase in yield, δy, produced by an increment of dose, δx, is given by:

$$\delta y=b(y_s-y)\delta x \qquad (3)$$

which is explicable if the effect of an ion striking a surface zone of nitrates is to produce an extent of conversion to nitrite and oxygen which undergoes no net change from subsequent bombardment by another ion. On this model the constant b is a measure of the mean effective cross-section of the ion (calculated as 3·1 Å² from Fig. 1 for 2 keV D^+ ions), and the saturation yields, which fluctuate by a factor of about three over the nitrates used, depend partly on the depth to which chemical effects occur but chiefly on the degree of reaction achieved within an individual bombarded zone. There is evidence, cited previously[1], that complete decomposition of alkali metal

Table 1. Relative Yields from the Wide Beam (1 in. diam.)

	Dose (coulombs × 10^3)	Yield (moles × 10^7)	Yield / Yield from KNO_3

	47·2	5·94	0·70	

nitrates cannot be achieved by prolonged radiolytic or thermal treatment.

In calculating yields of displaced oxygen atoms by a collision theory model, considerably higher values would be obtained if it were assumed, as seems reasonable, that all fast displaced atoms of sufficient kinetic energy may cause decomposition of the nitrate group. Since energetic collisions with nitrite ions may be expected to cause their decomposition, the evidence that little further degradation occurred on prolonged bombardment[1] indicates that reactions must occur by which the nitrite ion is re-formed, which seems probable since the fragments produced by collision processes will be in close proximity. Other reactions of primary products are also to be expected and the observed yields can only be correlated with those to be computed on the above assumption if a process such as:

$$NO_2^- + O \rightarrow NO_3^- \qquad (4)$$

occurs to a significant extent. It would seem probable that the differing extents of decomposition produced in the alkali metal nitrates is determined mainly by the relative importance of reaction (4), since only slight differences in yield are predicted from the calculations.

A quantitative treatment of the reactions of the primary species would require knowledge of the initial distributions, which might be estimated by considering probable collision sequences, and of the rate constants and diffusion coefficients applicable in the track where there is excess vibrational energy due to that lost in non-disruptive collisions. Since in a relatively open lattice the probability of a recombination reaction will be reduced, such calculations might be expected to predict the largest yields from potassium nitrate. However, the relation between yield and crystal volume per molecule is scarcely likely to be a direct proportionality so that formal agreement is unlikely with the expressions obtained[1] using the empirical factor $\theta = V(MNO_3)/V(KNO_3)$. This parameter, which was introduced on the premise that the Bohr equations for atomic collisions might not apply in a tightly bound lattice, is in any event unsatisfactory since it uses potassium nitrate as an arbitrary standard.

The high temperature increase in the yield has been correlated with the occurrence of secondary electron emission. The low temperature enhancement, which is most marked at low doses and thus corresponds to an increase chiefly in b, may be due to a diminished extent of reaction (4) in the track periphery on account of the rapid cooling.

It may be noted from Table 2 (ref. 1) that in all cases higher values of $G(NO_2^-)$ are obtained from D^+ ions and α-particles than from X-rays or γ-rays. The difference is greatest in the case of those nitrates which, having little 'free space' within the lattice, are the most stable towards X- or γ-radiolysis, so Hochenadel[2] suggested that local heating in the α-particle tracks promotes the escape of fragments from the cage, especially where this is retarded by a closely-bound lattice. The similarities in the G values from α-particles and D^+ ions, which probably reflect similar consequences of thermal effects, is not surprising in view of the comparability of the linear energy transfer of α-particles (34 eV/amp) with that of the fast displaced atoms, of which O atoms of linear energy transfer around 10 eV/amp are the most numerous.

Some recent work[3] on the velocity distribution of sputtered metal atoms provides evidence for the generation of thermal spikes by ion bombardment. For example, it was estimated that 4 per cent of the gold atoms sputtered by 43 keV argon ions are evaporated from heated spikes, the temperature of which is deduced to be about 1,750° K.

Regarding the apparent dose-rate effects reported in Fig. 4 (ref. 1), the increase in the yield from a constant small dose with increasing ion current shown in the upper curve may be attributed to space charge spreading since the variations could be predicted by applying the charts of Thonemann[4] and the dose-yield curve of Fig. 1 to a beam of bell-shaped cross-section, taking the initial half-width as ¼ in. on the basis of source and lens geometry. As only a very slight effect is to be expected under the conditions listed for the lower curve, where the beam area is reduced and the mean dose per unit area increased, each by a factor of 4, it is rather surprising that such results should be obtained if the current is varied by a means which cannot otherwise affect the beam intensity profile and so an alternative explanation is required.

I thank S. N. Brown, who performed some additional experiments.

Height Equivalent to a Theoretical Plate of Tubular Gas Chromatographic Columns lined with a Porous Layer

In a former publication[1] the following expression was derived for the height equivalent to a theoretical plate (HETP), h, of a tubular column of radius r:

$$h = 2\frac{D_g}{v} + \frac{1+6k+11k^2}{24(1+k)^2}\frac{r^2v}{D_g} + \frac{k^3}{6(1+k)^2}\frac{r^2v}{K^2D_l} \qquad (1)$$

where: v = average carrier gas velocity; D_g = molecular diffusion coefficient of component in the gas phase; D_l = molecular diffusion coefficient of component in the liquid phase; k = capacity ratio of liquid over gas phase; r = radius of tubular column; K = partition coefficient.

When the ratio of the last two terms, which is of the order of $\frac{D_g}{K^2D_l}$, is high, it becomes beneficial to disperse the retaining liquid film in a porous layer, of thickness αr, in order to make the time of diffusion in the liquid phase negligibly small.

This porous layer acts as a fixed phase for the inert component as well, and the HETP of such a lined column can be calculated as follows under the assumption that the layer is sufficiently porous, and the size of the average interstices sufficiently larger than the mean free path, so that the molecular diffusion constant within that layer for inert molecules is practically equal to D_g.

Let r designate the inner radius of the porous layer, that is, the radius of the unobstructed gas path. For α small, the HETP of inert components can be calculated by inserting a virtual capacity ratio of value:

$$k_{v_0} = 2\alpha$$

and by making $K = 1$ and $D_l = D_g$ in the above formula.

Since the total relative column capacity has been increased from unity to $1 + k_{v_0} = 1 + 2\alpha$ for inert components, the total relative column capacity should be increased from $1+k$ to $(1+2\alpha)\cdot(1+k)$ for retained components, so that the virtual capacity ratio for these should be:

$$k_v = (1+2\alpha)k + 2\alpha$$

For the partition coefficient K, we should now use the virtual coefficient:

$$K_v = \frac{k_v}{2\alpha} = 1 + k + \frac{k}{2\alpha}$$

while the liquid diffusion term, D_l, should be replaced by D_l/K_v.

Making these substitutions in (1), and neglecting terms in powers of α higher than unity, we obtain for the HETP of a porous tubular column:

$$h = 2\frac{D_g}{v} + \frac{1}{24}\left[\frac{1+6k+11k^2}{(1+k)^2} + 8\alpha + \frac{16k\alpha}{(1+k)^2}\right]\frac{r^2v}{D_g} \quad (2)$$

This formula indicates, for example, that for $k = 3$, and for values of α as high as 0·1, that is, for tubular columns in which the porous layer cross-section equals one-fifth of the unobstructed cross-section, the term within the bracket is increased from 7·4 to 8·5, that is, the dynamic diffusion term is 15 per cent larger than it would be in an ideal tubular column in which the diffusion time within the liquid layer would be negligible. This means also that the performance index achievable in such a column would be 15 per cent higher than theoretically possible in an ideal column.

Isomers of Hexasulphur Diimide

WEISS has reported[1] that he had obtained a little of a new compound $S_6(NH)_2$, hexasulphur diimide, from the products of the reaction between ammonia and disulphur dichloride[2]. He later assigned it the structure (I) on the evidence of an X-ray analysis[3].

I II III IV V

From the products of the same reaction, in formdimethylamide solution[2], I have now isolated no fewer than three compounds of the formula $S_6(NH)_2$, which I believe to be the isomers (I), (II) and (III). For their preparation, 15 g of the crude reaction product (consisting mainly of sulphur and heptasulphur imide) were subjected to chromatography on a silica-gel column 40 cm × 8 cm, eluting with carbon disulphide (8 l.). The sulphur came off first, followed by heptasulphur imide and then by the three hexasulphur diimides, which were cleanly separated from the heptasulphur imide but only partly separated from each other. Pure specimens of the isomers were obtained by two recrystallizations, from carbon disulphide, of appropriate combinations of chromatographic fractions The separations were monitored by infra-red absorption spectroscopy. The diimides all crystallized well as colourless rhombs with a tendency to needle habit.

Some data on the separation and properties of the diimides, identified as *A*, *B* and *C*, are given in Table 1.

The argument for the structures assigned is as follows. *A* gives an infra-red absorption spectrum which differs from that of S_7NH, structure (V), only in being twice as intense and in showing a slightly shifted S—N frequency. *B* shows a split S—N frequency, and *C* a greater split. Therefore the interaction between the two imino groups, and their proximity, must increase from *A* through *B* to *C*. Structure (IV) I exclude because it is difficult to see how it could be formed by the reactants. These assignments are, of course, tentative and require confirmation.

My compound *A* is almost certainly that described by Weiss.

Application of Atomic Absorption Spectroscopy to the Determination of Cobalt in Steel, Alloy Steel and Nickel

THE determination of cobalt at low concentration has become important in relation to materials associated with atomic energy uses. Specifications for steels for such purposes require 0·02 per cent maximum and in some cases, 0·01 per cent maximum cobalt.

Because of this the British Standards Institute has recently produced a method—BS1121: Part 42: 1961—suited to the range up to 0·04 per cent cobalt for which a reproducibility of ± 0·001 per cent up to 0·01 per cent and ± 0·002 per cent up to 0·04 per cent cobalt is claimed. To obtain the desired precision, a rather involved and longthy method is required, including a zinc oxide separation, precipitation of cobalt with α-nitroso β-naphthol, and re-solution of cobalt with final photometric determination using nitroso *R* salt.

Notes. (1) All prominent bands between 2·5μ and 15μ are listed. Wave-lengths are correct to ±0·02μ. Figures in italics are optical densities, at band maxima, of 0·023 molal solutions in carbon disulphide; a 0·2-mm cell was used.
(2) Approximate values only, by cryoscopy in tertiary butanol (semi-micro).
(3) Outer limits of band, and band maximum (latter in italics).

In view of the quoted atomic absorption detection limit of 0·2 p.p.m. for cobalt by Allan[1] and Gatehouse and Willis[2], the determination of cobalt by this approach was investigated. Equipment used was that described by Box and Walsh[3]. The cobalt lamp was a commercial hollow cathode supplied by Ransley Instruments. Allan[4] stated the strongest line in absorption is 2407·2 Å and this was used in the work. The monochromator is required to resolve this line from another strong line at 2411·6 and a weak line at 2404·2 Å.

Using 2 g of sample dissolved in hydrochloric acid and oxidized with nitric acid similarly to the BS1121: Part 42 solution procedure, diluting to 50 ml. and using a 10-cm slightly lean air-acetylene flame absorption path, a sensitivity of 0·001 per cent cobalt was obtained and results on plain carbon, low alloy, stainless and silicon steels from the range of B.C.S., N.B.S. standard samples and a number of other samples were within the Part 42 agreement tolerance against certificate values and/or results obtained on the same samples by Part 42.

At the low wave-length there was some absorption by the high iron concentration and calibration series required to be based on cobalt-free iron with added cobalt.

Using the BS1121: Part 30: 1954 solution treatment where 0·5 g of sample is dissolved in 20 ml. phosphoric–sulphuric acid mixture, oxidized with nitric acid and diluted to 100 ml., tungsten was retained in solution and satisfactory results were obtained on a wide range of low- and high-alloy steels, high-speed steels and pure nickel, results generally agreeing with certificate results and/or those obtained on the same sample by Part 30 within the tolerance reproducibility limits of Part 30 (a direct photometric method using nitroso *R* salt).

Thin-layer Chromatography of Some Food Colours on Silica Gel

Thin-layer chromatography, first devised by Stahl[1], is a very useful technique for the separation and identification of organic compounds on a micro-scale. Among its many advantages is its speed, requiring at the most about 90 min to complete one chromatogram. As yet, we are aware of only one report in the literature describing its use for water-soluble dyestuffs. Wollenweber[2] has described chromatographic systems for dyestuffs on the West German permitted list of food colours using cellulose powder as the thin layer. Here we describe the use of silica gel as an adsorbent for the thin layer chromatography of sulphonated dyestuffs.

Paper-chromatography of water-soluble dyes is quite well known[3]. A large number of solvent systems have been devised for their separation. Generally these contain large amounts of water. In our experience thin layers of silica gel often flake off the glass supporting plate with solvent systems containing more than 10 per cent by volume of water. We have therefore devised solvents which will separate the dyes examined and which contain minimal amounts of water.

The dyes examined were among those present on the list of permitted food colours for New South Wales. They are listed in Table 1 with their Colour Index number and their R_{mo} values for each satisfactory solvent. R_{mo} is defined as:

$$\frac{R_F \text{ of dye}}{R_F \text{ of methyl orange}}$$

This was found to give consistent values in contrast to R_F values which were unreliable, varying greatly with only small differences in composition of any of the solvents used.

The chromatograms, in general, required no more than 30 min for completion and gave excellent separations. Trial mixtures were well resolved. Only indigo carmine gave poor results, either streaking, fading, or not moving from the starting line. This does not happen on paper chromatograms of this dye in similar solvents. In fact our sample of this dye splits into three components. Erythrosine showed at least two components in solvents *B*, *D*, and *E*, and three in solvent *C*. Other dyes revealed as mixtures were chlorazol pink *Y*, chocolate brown *FB*, and brown *FK*. Chlorazol pink *Y* may be a mixture of isomeric sulphonic acids[4], chocolate brown *FB* is a mixture of dyes resulting from the coupling of morin and maclurin with diazotized sulphanilic acid, while brown *FK* is a *bis*-azo dye derived from the coupling of *m*-phenylenediamine with diazotized sulphanilic acid. The separation of these substances into several components is, therefore, only to be expected and confirms the usefulness of the thin-layer technique. Another interesting point is the separation of the isomeric pairs scarlet *GN* and ponceau *SX*, and yellow *FCF* and orange *GGN*, which are easily distinguished.

This work forms part of a programme supported by the National Health and Medical Research Council of Australia, the Council of the Australian Food Technologists' Associations and grant *EF*-258 from the U.S. National Institutes of Health. We thank Prof. S. E.

Crystal Structures of *Bis*-(Salicylaldehydato)-copper(II) and *Bis*-(8-Hydroxyquinolinato)-copper(II)

Anhydrous *bis*(salicylaldehydato)copper(II) and *bis*(8-hydroxyquinolinato)copper(II) were obtained by precipitation of the complexes from aqueous solution and recrystallization from water-free chloroform and chlorobenzene respectively. Both compounds formed bronze-green crystals. Their structures have been determined from single-crystal X-ray photographs using copper $K\alpha$-radiation. Both compounds were found to crystallize in the monoclinic space group $P2_1/c$, details being as follows:

Bis(salicylaldehydato)copper(II) had unit cell dimensions: $a = 8{\cdot}77$, $b = 6{\cdot}21$, $c = 12{\cdot}33$ Å, $\beta = 117{\cdot}4°$. The structure was solved by three-dimensional Fourier and Patterson methods and refined by the diagonal least-squares technique. There are two centro-symmetric $(C_7H_5O_2)_2Cu$ groups in the unit cell, the metal ion being co-ordinated to the oxygen atoms in a square planar configuration with O—Cu—O angle within the chelate rings 93·0° (e.s.d. 0·4°). The Cu—O distances are 1·87[5] and 1·93[2] Å for the phenolic and aldehydic oxygen atoms respectively (e.s.d. 0·017 Å in each case), and the next nearest atoms to the copper are aromatic carbon atoms from neighbouring molecules at a distance of 3·24 Å above and below the molecular plane.

The observed structure of *bis*(salicylaldehydato)copper-(II) confirms Stackelberg's conclusion from unit cell measurements alone[1] that the molecule is square planar. The distance of 3·24 Å to the nearest neighbours of the copper atom above and below the molecular plane excludes any intermolecular interaction which could be interpreted as giving the copper atom a co-ordination number of six, such as is found in *bis*(acetylacetonato)-copper(II)[2]; *bis*(salicylaldehydato)copper thus adds to the still small group of copper(II) compounds in which the metal atom has square planar stereochemistry.

Bis(8-hydroxyquinolinato)copper(II) had unit cell dimensions: $a = 10{\cdot}90$, $b = 8{\cdot}61$, $c = 18{\cdot}16$ Å, $\beta = 102{\cdot}0°$. Approximate co-ordinates of the metal atoms were obtained from the three-dimensional Patterson function and the rest of the structure solved by Fourier syntheses; refinement was carried out by the differential Fourier method. There are four $(C_9H_6ON)_2Cu$ groups in the unit cell, forming two dimeric units, one oxygen atom of each $(C_9H_6ON)_2Cu$ group completing a square pyramidal arrangement about the copper atom of another. Each copper atom is thus surrounded by two nitrogen atoms at 1·94[5] Å and two oxygen atoms at 2·00 Å very nearly in a plane and a third oxygen atom at the apex of the square pyramid at 2·85 Å; the Cu—Cu distance in the dimeric unit is 3·49 Å (all distances e.s.d. 0·03 Å) (Fig. 1).

Bridged bimolecular structures with tetragonal pyramidal 5 : co-ordination of the metal atoms have been observed in several other copper(II) complexes. Thus, in *bis*(dimethylglyoximato)copper(II)[3] two planar molecules are linked by co-ordination of one of the oxygen atoms of each to the copper atom of the other, giving an intermolecular Cu—O distance of 2·43 Å, and in dimethylglyoxime-dichloro-copper(II) there is a similar chlorine bridge between the copper atoms of a pair of molecules[4].

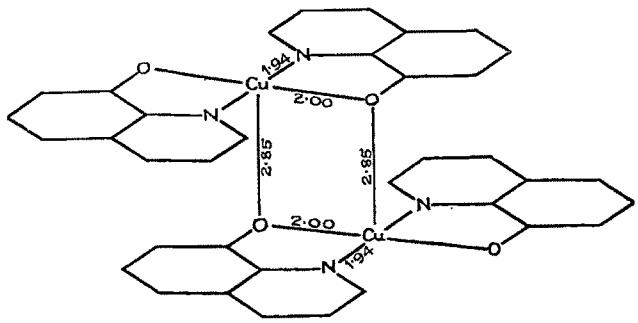

Fig. 1

In disalycilidine-ethylenediamine-copper(II)[5] dimerization occurs through one of the oxygen atoms, the remainder of the molecule being distorted to allow a Cu—O distance of 2·41 Å in the bridge.

In *bis*(8-hydroxyquinolinato)copper(II) only slight distortion is observed and the bridging Cu—O distance of 2·85 Å is correspondingly much longer, though still too short to be considered non-bonding. Observations of the spectra of this complex support the interpretation of this distance as representing a weak co-ordinate bond, the visible region, solid-state, reflectance spectrum being shifted about 70 mμ to longer wave-lengths as compared with chloroform solutions; whereas the reflectance and solution spectra for *bis*(salicylaldehydato)copper(II) are virtually the same. A similar shift to longer wave-length has been observed in 5 : co-ordinated adducts of *bis*-(acetylacetonato)copper(II) and related compounds[6].

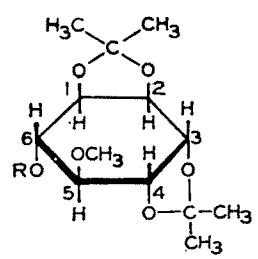
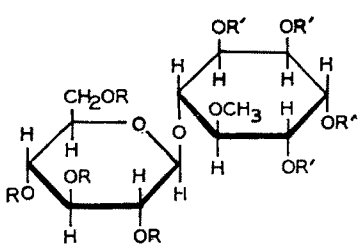
A Synthetic Cyclitol Glycoside



The synthesis of cyclitol glycosides is of interest because of the natural occurrence of these substances as such (galactinol) and as structural moieties of several antibiotics and phospholipids[1,2]. In this laboratory, attempts have been made to couple activated forms of glucose with protected derivatives[3] of *myo*-inosamine-2 and, more recently, (+)-pinitol. The former efforts were unsuccessful; but the latter provided a glucoside (V) of pinitol in fair yield.

The initial condensation was effected by the Koenigs–Knorr method. Diacetono-(+)-pinitol, which has been shown to be 1,2 : 3,4-di-*O*-isopropylidene-5-*O*-methyl-D-inositol (I)[4] (the numbering used here is that of Fletcher, Anderson and Lardy, reviewed in ref. 1), was prepared by the method of Anderson[5]. It was dissolved in alcohol-free chloroform and the solution was stirred for 1 h with dry silver oxide and anhydrous calcium sulphate ('Drierite'), then tetra-*O*-acetyl-α-D-glycopyranosyl bromide and iodine were added. Stirring was continued for 24 h, the reaction vessel being protected from light. Inorganic salts were removed by filtration on a 'Celite' pad, which was washed with chloroform, and the filtrate and washings were concentrated to a syrup under vacuum. The crystalline condensation product was obtained by dissolving the syrup in a minimal volume of hot methanol, adding water to



turbidity, and cooling. After recrystallization the compound melted at 167°–168°, and had $[\alpha]_D^{20}$ −3° (c=7, $CHCl_3$). Found: C, 53·02; H, 6·64. Required for $C_{27}H_{40}O_{15}$: C, 53·64; H, 6·67.

It must be assumed that condensation occurred at the only free hydroxyl in I, and it may be further assumed that steric inversion took place at the anomeric carbon of glucose, as usual, to give a β-glucosidic linkage. The condensation product is therefore formulated as 1,2 : 3,4-di-*O*-isopropylidene-5-*O*-methyl-6-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-D-inositol (II). The best yield of II (56 per cent of the theoretical from diacetonepinitol) was obtained with a reaction mixture of the following composition, per gram of diacetonepinitol : chloroform, 50 ml.; silver oxide, 1·2 g; 'Drierite', 20 g; tetraacetylglucosyl bromide, 2 g; and iodine, 0·2 g.

For removal of the isopropylidene groups, II was heated in 25 vol. of 80 per cent (v/v) aqueous acetic acid at 100° (thermostat) for 18 h. The resulting compound, which must be 5-*O*-methyl-6-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-D-inositol (III), was a syrup. On treatment with acetic anhydride in pyridine at room temperature it furnished, in essentially quantitative yield, the octaacetyl derivative of V, 1,2,3,4-tetra-*O*-acetyl-5-*O*-methyl-6-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-D-inositol (IV), needle-like prisms from aqueous methanol, m.p. 135–136°, $[\alpha]_D^{25}$ −31° (c=1·9, $CHCl_3$). Found: C, 49·89; H, 5·79; CH_3O, 4·60. Required for $C_{28}H_{37}O_{18}(CH_3O)$: C, 50·29; H, 5·82; CH_3O, 4·48.

I, R = H; II, R = tetra-*O*-acetyl-β-D-glucopyranosyl;

III, R = CH_3CO, R' = H; IV, R = R' = CH_3CO; V, R = R' = H

The octaacetate was deacetylated by refluxing it in 36 volumes of 0·2 N methanolic sodium methoxide for 2 h, after which the methanol was replaced by water, and sodium ions were removed by passage of the solution over 'Amberlite *IRC*-50 (H^+)'. Evaporation of the deionized solution gave syrupy pinitol β-D-glucoside (6-*O*-β-D-glucopyranosyl-5-*O*-methyl-D-inositol, V). Freeze-dried glucoside dissolved in 2 volumes of methanol is precipitated by 8 volumes of *n*-butanol as an amorphous solid melting from 125–140°, but the compound has so far not been crystallized. The specific rotation, $[\alpha]_D^{25}$, in water is +35° (c= 0·8, established by quantitative determination of the glucose in a hydrolysed aliquot).

The glucoside does not react with Somogyi's copper reagent or with glucose oxidase; but yields glucose-positive solutions on hydrolysis with boiling 2 N sulphuric acid (8 h). A portion of the hydrolysate from which glucose was removed by chlorite oxidation[6] and subsequent deionization showed, when chromatographed on Whatman No. 1 paper with acetone/water 9 : 1 (v/v), a single silver-reducing spot with the same mobility as authentic (+)-pinitol. The observed value for the specific rotation of the glucoside supports the assignment of the β-configuration to the glucosidic carbon. The figure is somewhat higher than those observed for simple alkyl β-D-glucopyranosides (−34 to −41°), owing to the positive contribution of the pinitol moiety (free pinitol, $[\alpha]_D$ +65°), but much lower than would be predicted for an α-glucoside of (+)-pinitol.

Reaction of Di-isobutyl Aluminium Hydride with Stannic Chloride

General methods for preparation of organo–tin compounds of divalent tin have been reviewed by Gilman *et al.*[1]. The most usual methods include reaction of stannous chloride with a Grignard reagent or lithium alkyl and reduction of a dialkyl tin IV dichloride with sodium amalgam. In addition, reaction of sodium triethoxylalumino hydride with organo–tin IV halides in certain circumstances leads to formation of divalent organo–tin compounds[2].

Reaction of stannic chloride with a reagent which combines alkylating as well as reducing action on tin IV halides does not appear to have been investigated. Dialkyl aluminium hydrides fulfil this requirement and the interaction of di-isobutyl aluminium hydride with stannic chloride has been studied. Gilman *et al.*[1] mention the reaction of triethylaluminium with stannic chloride as leading to diethyl tin II, but this arises from a mistake in the *American Chemical Abstracts*[3]; the original patent specification[4] deals with the synthesis of hydrocarbon tin IV compounds. In the investigation recorded here, a solution of di-isobutyl aluminium hydride (4·0 g) in *cyclo*hexane (50 ml.) was added dropwise to a solution of stannic chloride (16·0 g) in *cyclo*hexane (200 ml.). The reaction mixture was maintained under a stream of nitrogen, stirred rapidly and cooled in an ice bath. On completion of the reaction a biscuit-coloured solid settled in the reaction vessel. The reaction mixture was filtered under nitrogen and the residue washed with *cyclo*hexane (50 ml.) followed by carbon tetrachloride (50 ml.) to remove excess stannic chloride or organo–tin IV chlorides formed during the reaction. The residue (6·0 g) was pumped at diminished pressure to remove solvent and extracted with chloroform (100 ml.). The resulting chloroform solution varied in colour from amber to red while the white residue (2·0 g) consisted substantially of stannous chloride. After filtration under nitrogen, chloroform was removed by vacuum distillation at 0·1 mm pressure. When most of the solvent was removed the temperature was raised to 100° C and the product (4·0 g) obtained as a red to amber friable mass[5], sparingly soluble in hydrocarbon solvents, slightly soluble in carbon tetrachloride, readily soluble in chloroform. On heating, the product charred at 220° C and decomposed in acid solution, immediately reducing silver nitrate solution. Careful oxidation with dilute nitric acid, followed by titration with silver nitrate, revealed ionic chloride present in 1 : 1 ratio with tin. However, even after two days' pumping, several samples retained a more or less definite amount of chloroform. $(4(C_4H_9)SnCl)\ CHCl_3$: requires C, 21·15; Cl, 25·76; H, 3·84 per cent. Found on three sample preparations: C, 20·16, 21·00, 21·08; H, 4·0, 4·1, 4·0; Cl, 25·82, 25·73, 26·0 per cent.

In an attempt to prepare $(C_4H_9)_2Sn$ the amount of di-isobutyl aluminium hydride added was increased to 8·0 g, but a black unresolved mixture was obtained.

BIOCHEMISTRY

Production of a Cephalosporinase by *Pseudomonas pyocyanea*

Crude preparations of penicillinase from *Bacillus cereus* N.R.R.L. 569, unlike the purified penicillinase from this organism or crude penicillinase from *Staphylococcus aureus* R_1, have been shown to catalyse the hydrolysis of the β-lactam ring of cephalosporin *C* and other derivatives of 7-aminocephalosporanic acid at a significant rate. The enzyme responsible for this hydrolysis was termed a cephalosporinase[1,2]. The maximum rate of hydrolysis (V_{max}) of cephalosporin *C* obtained with a crude enzyme from *B. cereus* was only 5 per cent of that of benzylpenicillin, but this value increased to 33 per cent after selective inactivation of penicillinase in aqueous solution at 60° C. Subsequent studies were made with a crude enzyme from *Bacillus subtilis* N.C.T.C. 6346, induced with cephalosporin *C* and freed from the cells by the action of lysozyme[3]. With this enzyme preparation V_{max} for cephalosporin *C* was about 10 per cent that for benzylpenicillin, but attempts to separate a cephalosporinase from a penicillinase, or selectively inactivate a penicillinase, were unsuccessful.

We have found that a strain of *Pseudomonas pyocyanea* (N.C.T.C. 8230) produces an enzyme which shows a much greater value of V_{max} with cephalosporin *C* or 7-phenacetamidocephalosporanic acid as substrate than with penicillin *N* (which has the same D-α-aminoadipoyl side-chain as cephalosporin *C*) or benzylpenicillin. When *Ps. pyocyanea* was grown in nutrient 'Oxoid' broth the penicillinase or cephalosporinase activity of the culture fluid or whole culture was too small to be detected by the manometric method. Furthermore, no activity was detected after a culture had been subjected to ultrasonic disintegration (60 W at 0° for 2–15 min) or freeze-pressing in an 'X-press'[4]. No detectable amount of enzyme was induced by concentrations of benzylpenicillin sufficient to cause maximum induction of penicillinase in *B. cereus* (1 μg/ml.) or by concentrations of 2 : 6-dimethoxyphenylpenicillin (1 μg/ml.) or cephalosporin *C* (10 μg/ml.), which showed a strong inducing activity in *Staphylococcus aureus* R_1[2]. However, after very high concentrations of benzylpenicillin (10 mg/ml.) or cephalosporin *C* (10 mg/ml.) had been added to a growing culture of the organism, considerable enzyme activity appeared in the culture fluid. A significant but smaller amount of enzyme appeared after the addition of 7-phenacetamidocephalosporanic acid (5 mg/ml.). In some, but not in all, of these experiments the cells underwent partial lysis.

With the crude enzyme, V_{max} at *p*H 7·0 was more than ten times as great for cephalosporin *C* and 7-phenacetamidocephalosporanic acid as for penicillin *N* and benzylpenicillin. But with all these substrates the Michaelis constants were very much higher than those for penicillin *N* or benzylpenicillin with penicillinase from *Staph. aureus* or *B. cereus*. Characteristic changes in ultra-violet absorption spectra, which accompanied the hydrolysis of cephalosporin *C* and deacetylcephalosporin *C* lactone, indicated that the enzyme involved was a β-lactamase.

2 : 6-Dimethoxyphenylpenicillin (methicillin) proved to be relatively highly resistant to the enzyme and a powerful inhibitor of the action of the enzyme on cephalosporin *C*, 7-phenacetamidocephalosporanic acid and benzylpenicillin. Similarly, 3-*o*-chlorophenyl-5-methyl-4-isoxazolylpenicillin (orbenin) was highly resistant to hydrolysis. This compound, and to a lesser extent 6-aminopenicillanic acid and 7-aminocephalosporanic acid, also inhibited the hydrolysis of cephalosporin *C*. α-Aminobenzylpenicillin (ampicillin) was hydrolysed at a rate which was about 15 per cent of that with benzylpenicillin in the concentration used (1 mg/ml.).

The behaviour of 2 : 6-dimethoxyphenylpenicillin to the enzyme from *Ps. pyocyanea* is in striking contrast with its failure to inhibit the hydrolysis of penicillin *N* or benzylpenicillin by staphylococcal penicillinase[2,5], but is analogous with its inhibitory action on a penicillinase from *Klebsiella aerogenes*[6]. The effect of the 2 : 6-dimethoxybenzoyl side-chain on the enzyme from *Ps. pyocyanea* is paralleled in the behaviour of 7-(2 : 6-dimethoxybenzamido) cephalosporanic acid, which is also resistant to hydrolysis by this enzyme. Whether the crude enzyme consists of more than one β-lactamase remains undetermined.

An enzyme produced by a strain of *Enterobacter cloacae* has recently been reported to be highly active against cephalosporin *C* but to have little, if any, activity against benzylpenicillin[7]. It appears that enzymes able to degrade cephalosporin *C* have not been found in *Klebsiella*, but are distributed within a number of other genera of the Enterobacteriaceae and that the species most resistant to the antibiotic are among those which produce these enzymes[7]. However, we have no evidence which would suggest that the production of penicillinases or cephalosporinases is primarily responsible for the high resistance of *Pseudomonas pyocyanea* to any of the penicillins or cephalosporins tested. Methicillin and orbenin, which were relatively insensitive to the enzyme from *Ps. pyocyanea*, and ampicillin, which was hydrolysed at a relatively low rate, showed no significant activity against this organism.

Phosphoprotein as an Intermediate in Cerebral Microsomal Adenosine-triphosphatase

Microsomal and cell membrane fractions from cerebral cortex contain a powerful ATP-splitting system, activated by Mg^{2+}, Na^+ and K^+ and inhibited by the cardiac glycoside ouabain[1–6]. The nature of the ATP-splitting reaction is not clear; but recently it has been reported that a phosphorylated intermediate is involved in the splitting of ATP by guinea pig kidney cortex[13], human erythrocyte membranes[14] and the electric organ of the electric eel[15]. This note provides evidence that phosphoprotein from cerebral cortex becomes labelled during the splitting of $AT^{32}P$ by the ATPase, and that the time-course of uptake of labelled phosphate from ATP into the phosphoprotein fraction and into inorganic orthophosphate is indicative of the phosphoprotein being a precursor of inorganic phosphate.

In principle, the experiment consisted of the brief incubation of $AT^{32}P$ with a brain enzyme preparation in

media of various compositions. The reaction was stopped with trichloroacetic acid (TCA), and the specific activity of the inorganic phosphate, and of the various phosphate fractions of the acid-insoluble residue, determined. In order to provide sufficient material for analysis of the acid-insoluble residue, the enzyme preparation consisted not solely of microsomes but of a post-mitochondrial supernatant, including the microsomes, prepared by dispersing guinea pig cerebral cortex in 4 volumes of ice-cold 0·32 M sucrose, buffered at *p*H 7·4 with 10 mM *tris*-hydrochloric acid, with a 'Teflon'-glass homogenizer, and centrifuging once at $10{,}000g_{av.}$ for 15 min.[4]. The supernatant so obtained was aged at −18° for at least four days prior to use[3]. According to Deul and McIlwain[3] such a preparation contains 40 per cent of the total MgKNaATPase activity of brain cortex, 82 per cent of the activity present in the post-mitochondrial supernatant being microsomal in origin. 2·5 ml. of this preparation was incubated at 37° in a medium containing 100 mM *tris*-hydrochloric acid, *p*H 7·4, 100 mM sodium chloride, 30 mM potassium chloride, 200 μM magnesium chloride and 50 μM EDTA. After pre-incubation for 5 min 0·5 μmole of β,γ-labelled $AT^{32}P$ (ref. 8), containing 2–5 × 10^5 counts/min, was added, giving a final incubation volume of 5·1 ml. Incubation was continued for up to 5 min. At various times 1-ml. samples of the reaction mixture were removed into 1 ml. lots of ice-cold 10 per cent (w/v) TCA, chilled in ice for 5 min and centrifuged. ATP and inorganic phosphate were determined[7,11] in the supernatant after separation by paper chromatography[9]. The acid-insoluble residue was fractionated[7,10] to yield five major groups of phosphate compounds, together accounting for the total acid-insoluble phosphate: phosphoprotein, phospholipid, nucleic acid phosphate, 'residual organic phosphate' and 'acid-precipitable phosphate'. Phosphate and specific activity (counts/min/μmole phosphorus) were determined for each fraction by methods already described[7,11]. The post-mitochondrial supernatant preparation used contained 85 per cent of the RNA, 72 per cent of the phosphoprotein, 30 per cent of the residual organic phosphate, 18 per cent of the phospholipid and 10 per cent of the acid-precipitable phosphate present in unfractionated cortex[7].

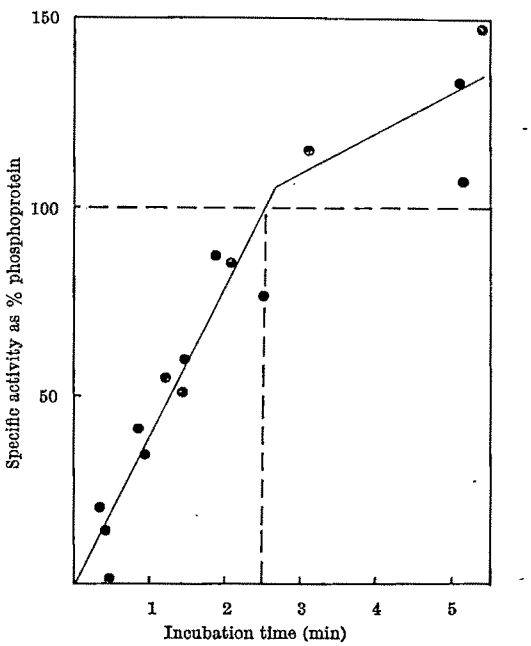

Fig. 1. Specific activity of inorganic phosphate as percentage of that of phosphoprotein at various times. Points from independent experiments

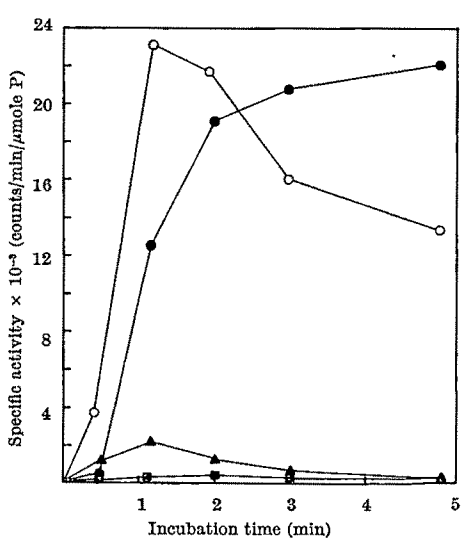

Fig. 2. Specific activity of phosphate fractions after various times. Graph typical of seven independent experiments. ●, Inorganic phosphate; ○, phosphoprotein; ▲, residual organic phosphate; ■, phospholipid, nucleic acid, acid-precipitable phosphate

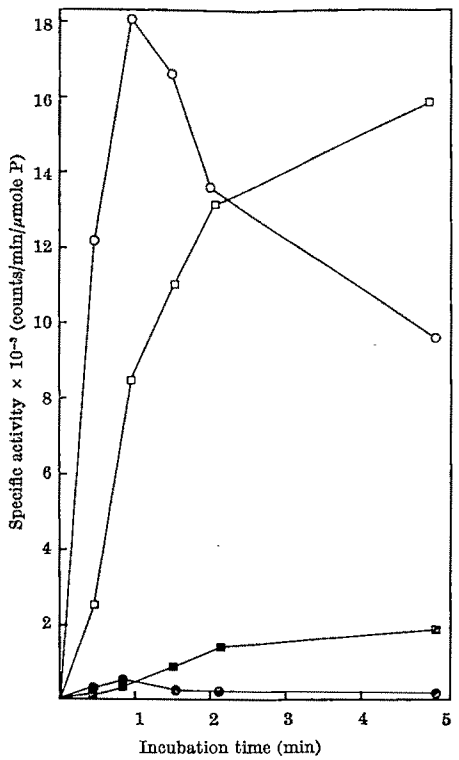

Fig. 3. Effect of Mg^{2+} and EDTA on incorporation of phosphate-32 into phosphoprotein and inorganic phosphate. ○, Phosphoprotein (standard medium); □, inorganic phosphate (standard medium); ●, phosphoprotein (medium—Mg^{2+}, + 1 mM EDTA); ■, inorganic phosphate (medium—Mg^{2+}, + 1 mM EDTA)

Under the incubation conditions described, ATP was rapidly broken down; 50 per cent of the radioactivity initially present as the γ-P of ATP was lost within 30 sec; after 5 min only 7 per cent remained. Examination of the other phosphate fractions showed that radioactivity appeared to a significant extent in only two, phosphoprotein and inorganic phosphate. After 2 min, the specific activity of residual organic phosphate, nucleic acid, acid-precipitable phosphate and phospholipid were respectively 3, 1·5, 1·5 and 0·5 per cent of phosphoprotein; in absolute terms, the counts incorporated into each of these four fractions were only 50–100 per cent above background. The time-course of incorporation into phosphoprotein and inorganic phosphate is shown in Figs. 1 and 2. Phosphoprotein rapidly became labelled, and for the first 2 min of incubation its specific activity

exceeded that of inorganic phosphate, afterwards declining. Incorporation into inorganic phosphate, on the other hand, increased steadily but more slowly, equalling the specific activity of phosphoprotein only after 2·5 min (Fig. 1), after which time it remained not greatly altered for periods of up to 15 min. 1 per cent of the radioactivity present in the γ-phosphate of ATP appeared in the phosphoprotein within 20 sec; after 5 min incubation 130 per cent of radioactivity initially present as γ-labelled ATP was found in the inorganic phosphate fraction, indicating that some β-labelled phosphate was also being removed from ATP. In 7 independent experiments, the maximum specific activity attained by the inorganic phosphate fell on or within 10 per cent of the curve representing phosphoprotein specific activity (Fig. 2); this relationship is characteristic[12] of a precursor-product relationship between phosphoprotein and inorganic phosphate, and indicates that during breakdown of ATP the major portion if not all of the liberated phosphate is transferred to phosphoprotein before being released as inorganic phosphate.

The microsomal ATPase is known to be absolutely dependent on Mg^{2+} (refs. 1–6). Omission of Mg^{2+} from the incubation medium was without effect on either phosphoprotein turnover or inorganic phosphate release; however, addition of the chelating agent EDTA at 1 mM effectively abolished incorporation into either phosphoprotein or inorganic phosphate (Fig. 3). Without EDTA, enough Mg^{2+} must remain bound to the large amounts of tissue present in the incubation medium to nullify the effects of the omission of Mg^{2+} from the medium. Similar observations have been made by Aldridge[5]. Incorporation into residual organic phosphate was also 70 per cent inhibited by EDTA; that into nucleic acid, phospholipid and acid-precipitable phosphate was not significantly changed.

These results are taken as providing evidence for the participation of a phosphoprotein fraction in the splitting of ATP by cerebral microsomes. Further details of the reaction, and its possible relation to the mechanism of cation transport, are being investigated.

A Hypothesis linking the Succinic Dehydrogenase System to an Intermediate of Oxidative Phosphorylation

Recent work[1] has demonstrated that incubation of heart mitochondria with succinate, inorganic phosphate and NAD for short periods at 0° yields a highly labile mono-phosphorylated derivative of NADH. This derivative, capable of phosphorylating ADP, has the properties required for an oxidative phosphorylation intermediate and it is suggested that during its formation the nicotinamide ring has been opened[1]. (Abbreviations: NAD and NADH, oxidized and reduced nicotinamide adenine dinucleotide, respectively; ADP and ATP adenosine-5′-di- and tri-phosphate, respectively.)

It is the purpose of this communication to suggest a hypothesis to account for the present experimental results. The hypothesis provides: (1) a pathway for the interaction of the succinic dehydrogenase system and NAD; (2) a reaction scheme with structures for the formation of the new monophosphorylated derivative of NADH and its participation in the phosphorylation of ADP.

Work[2] on the succinic dehydrogenase system has indicated that only one hydrogen of a removable trans pair[3] of hydrogens of L-chlorosuccinate and of succinate is exchanged with hydrogen of the medium during anaerobic exchange experiments. This evidence together with other evidence has led to the concept[2] that oxidation of succinate occurs by transfer of a hydrogen and a pair of electrons to succinic dehydrogenase, and in support of this it has been noted that succinate oxidation requires less oxygen when acetoacetate is present[4]. With the foregoing in mind, the hypothesis outlined schematically in Fig. 1 may be approached.

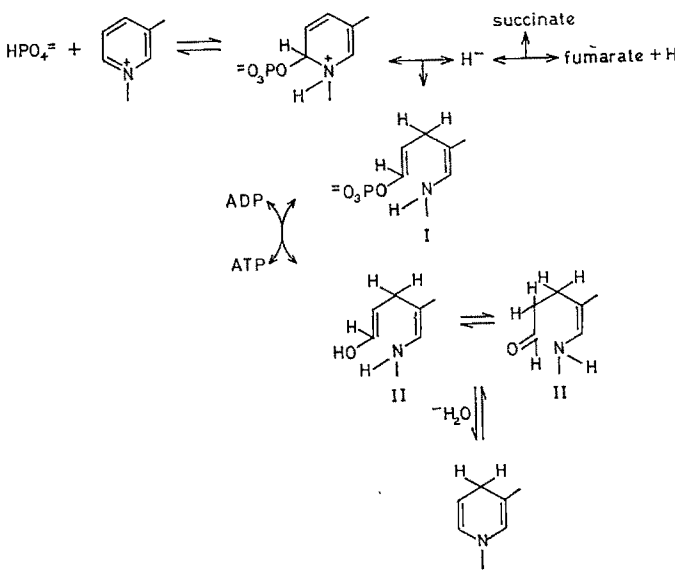

Fig. 1. Interaction of the succinic dehydrogenase system, NAD phosphate and oxidative phosphorylation

It is considered that first inorganic phosphate adds across an N to C double bond of the nicotinamide moiety of NAD, and the addition is written across the 1,6-double bond. This addition has previously been considered[5] as the starting point for oxidative phosphorylation and some supporting evidence has been adduced[6]. It is quite possible that such an addition is enzyme mediated and occurs via an NAD derivative. It is also possible that an enzyme group adds, and is afterwards displaced by, phosphate to yield compound I, the monophosphorylated derivative obtained by Griffiths and Chaplain[1]. Further, this addition may require ATP. In any event, addition is followed by transfer of a hydride ion from the succinic dehydrogenase system and this transfer results not only in reduction of the nicotinamide ring but also in ring opening to give compound I. Now, compound I, a vinyl phosphate, meeting the requirements of Griffith and Chaplain's observations, should be capable by analogy with phosphoenolpyruvate of phosphorylating ADP to ATP. Loss of the phosphate group by transfer to ADP results in transformation of compound I to compound II, which may be considered as a vinyl alcohol or an aldehyde or as both, in equilibrium. Compound II then undergoes ring closure to NADH. This is in keeping with the observations of Griffiths and Chaplain, who showed that on transfer of phosphate to ADP their monophosphorylated derivative was transformed into NADH.

It may be pertinent to enquire how the succinate half-cell with a much less negative E'_0 than the NADH half-cell[7] can be used for reduction of NAD and generation of ATP. It is possible if the driving force for the reaction comes from re-oxidation of NADH to NAD by a component of the succinic dehydrogenase system or the electron transport system which is greater in oxidation potential than the moiety reducing NAD.

Effect of Protein Depletion on Amino-acid Activating Enzymes of Rat Liver

Experiments conducted with ^{35}S-methionine and ^{14}C-lysine provide support of the hypothesis that depletion of protein induces a modification in the distribution and utilization of amino-acids for protein synthesis.

Protein-depleted animals exhibit, in fact, relatively less incorporation of labelled amino-acids in muscles and carcass and a greater incorporation in the viscera, particularly in the liver[1–3].

Two tentative hypotheses may be formulated to explain this effect in protein depletion: (1) Protein depletion exerts a direct effect on the incorporation of amino-acids, by enhancing protein synthesis in certain particular tissues or organs, as for example in the liver. (2) Protein depletion exerts its primary effect on the distribution of amino-acids either by modifying the flow of blood through the tissues, or by modifying the cell permeability in certain organs or tissues.

To test the validity of the first hypothesis, an examination of the different steps of protein synthesis in liver of animals, kept for varying amounts of time on a protein-free diet, was undertaken.

This communication describes work on the first step in protein synthesis, namely. activation of amino-acids.

Sprague–Dawley male rats, weighing 200 g, were divided into three groups and fed the following diets: group 1, *ad lib.* 20 per cent casein diet; group 2, *ad lib.* 0 per cent casein diet; group 3, 20 per cent casein diet pair-fed with rats of group 2.

The animals were kept on the protein-free diet up to a maximum of 60 days (after this time about 50 per cent of the animals died).

The amino-acid activating enzymes were determined, for practical reasons, on a 10,000*g* liver supernatant, since preliminary testing had shown that the values obtained with a 105,000*g* (ref. 10) and a 10,000*g* supernatant were in agreement.

The amino-acid activating enzymes were determined by measuring the rate of exchange between $P^{32}P$ and ATP in the presence of four added amino-acids, namely, leucine, isoleucine, tyrosine and methionine (5 μM each), according to the method of De Moss and Novelli[11].

The results were expressed as μM exchange/h/mg protein (Table 1) and, also, as μM exchange/h/mg DNA-P (Table 2). Calculation of results in terms of DNA-P content, which is proportional to the cell number, renders possible evaluation and comparison of the enzymatic activity in normal and protein-depleted animals, against a standard of reference, unaffected by the diet. The DNA-P content was determined according to the method described by C. B. Mendes and J. C. Waterlow[12].

Table 1. Effect of Protein Depletion on the Activity of Rat Liver Amino-acid Activating Enzymes
μM exchange/mg supernatant protein/h (The values are given as percentage of pair-fed controls)

Average 196	277	330	265

Each entry is the average value of three determinations for single rat.

Results in Table 1 show that the amino-acid-dependent exchange in the liver supernatant of protein-depleted rats is 3–4 times greater than in normal rats. These results can be explained, but only in part, assuming that a loss of liver proteins, other than amino-acid activating enzymes, occurred in the depleted animals.

Results in Table 2, expressed in terms of DNA-P content or, which is the same, in terms of average liver cell, substantiate this interpretation and clearly show that, following protein depletion, the level of amino-acid activating enzymes is not only fully retained but also undergoes a net increase.

Our results, obtained even with animals just before death (60 days' protein starvation), would suggest that the reported inability to build body proteins by dogs in an advanced stage of protein starvation[3] cannot be ascribed to a lessened efficiency of the first step, at least, of the machinery of protein synthesis.

In order to find out if the caloric intake might influence the amino-acid PP⇌ATP dependent exchange, the results relative to rats on 20 per cent casein diet, fed *ad lib.* or pair-fed with rats on the protein-free diet, were compared (Table 3). The results, similar in both cases, show that caloric restriction does not influence the amino-acid-dependent exchange.

Table 3. Effect of Calorie Intake on the Activity of Rat Liver Amino-acid Activating Enzymes

—	84	—	—
—	114	—	—
Average 100	112	102	113

Each entry is the average value of three determinations for single rat.

In conclusion, the sum of evidence obtained seems to suggest that protein depletion exerts a direct effect on protein synthesis, enhancing the activity of amino-acid activating enzymes, possibly through one of the following mechanisms: (1) *de novo* synthesis of the enzymes; (2) activation of pre-existing enzymes; (3) release of these enzymes from the particulate fractions of the cell, such as the mitochondria, where the presence of amino-acid activating enzymes has been demonstrated[13] to the soluble fraction.

We are inclined to believe that the third hypothesis may be discarded in so far that preliminary results, obtained with starving rats (Table 4), have not shown

Table 4. Effect of Six Days' Starvation on the Activity of Rat Liver Amino-acid Activating Enzymes
Values are given as percentage of control mean value μM exchange/mg DNA P/h

	No. of rats	%
Controls	5	100 ± 13
Starved rats	8	92 ± 14

any increase in the level of amino-acid activating enzymes in liver supernatant, although following starvation the mitochondria becomes structurally damaged.

An effect of protein depletion, mediated through the adrenals, may as well be discarded, since Smith *et al.*[14] have shown that cortisone is without effect on the amino-acid activating enzymes.

An attractive suggestion is that the level of these enzymes in the liver is regulated, almost homeostatically, by the total pool of free amino-acids. If this pool decreases, the level of liver amino-acid activating enzymes increases and, consequently, increases the fraction of amino-acids engaged in protein synthesis.

Finally, the results obtained seem to indicate that higher incorporation of amino-acids into liver proteins of protein-depleted rats[1–9] is due, at least partially, to the increased activity of liver amino-acid activating enzymes.

Inhibition by Trypsin Inhibitors of Dissociation of Embryonic Tissue by Trypsin

Trypsin is used extensively for dissociation of tissues and in the preparation of suspensions of living cells[1]. The cell-dissociating effect of this enzyme has been attributed to tryptic degradation of cell binding materials[1]; however, theoretically, other possibilities exist and the question whether the characteristic enzymatic properties of trypsin are actually involved in cell separation seems not to have been adequately tested, though such information would be of some general interest. Furthermore, since trypsin attacks selectively peptide linkages adjacent to lysyl and arginyl residues, clarification of the relationship between its cell-dissociating activity and its lytic properties would be useful in considerations of the mechanism of cell binding. Trypsin inhibitors offer a direct approach to this matter. It was reported that trypsin inactivated by diisopropylfluorophosphate (DFP) did not dissociate adult rat liver cells[2]. In the work recorded here, the effects of soybean and ovomucoid trypsin inhibitors on the dissociation by trypsin of embryonic tissue were examined. The interaction between these inhibitors and trypsin is considered to be specific and stoichiometric[3–5]; at concentrations equimolar to and higher than that of the enzyme, the inhibitors rapidly and completely abolish its tryptic activity. According to available results[3,5], the molecular weights of trypsin and trypsin inhibitors used in this investigation were of the following order of magnitude: trypsin—24,000; soybean trypsin inhibitor—24,000; ovomucoid trypsin inhibitor—28,000.

The tissue used in these assays was the neural retina from 10-day chick embryos. This thin sheet of non-fibrous and avascular tissue can be readily removed intact from the bisected eye. Half a retina from one eye was used in each assay. Standard cell dissociation procedure was adopted[6]. The tissue was incubated for 10 min in calcium- and magnesium-free solution (CMF[6]; Difco) at 38° C, then transferred into 1 ml. of trypsin solution, or into 1 ml. of solution of trypsin with the inhibitor, and incubated for 15 min at 38° C under 5 per cent carbon dioxide–air mixture. In all the tests trypsin (crystalline-lyophilized, Worthington Biochem. Corp.) was used as a 5·0 mg/ml. solution in CMF, that is, at about twice the minimal concentration required for effective dissociation of this tissue. Soybean trypsin inhibitor (5 times crystallized-lyophilized) and ovomucoid trypsin inhibitor (both from Worthington Biochem. Corp.) dissolved in CMF were added to the trypsin solution at concentrations listed in Table 1. Stability of intercellular adhesions in the treated tissue was tested by flushing the tissue briskly 15 times (for 30 sec) in and out of a Pasteur pipette (0·75 mm orifice), each intake measuring 0·5 ml. The resulting suspension was evaluated microscopically for the degree of cell separation, size of clusters and number of free cells.

Table 1

Tissue treated with:			Result
CMF			No dissociation
Trypsin 5·0 mg/ml. in CMF			Complete dissociation
Trypsin 5·0 mg/ml. in CMF with 15·0 mg/ml.	soybean trypsin inhibitor, or ovomucoid trypsin inhibitor		No dissociation
Trypsin 5·0 mg/ml. in CMF with 10·0 mg/ml.	,,	,,	No dissociation
Trypsin 5·0 mg/ml. in CMF with 5·0 mg/ml.	,,	,,	No dissociation
Trypsin 5·0 mg/ml. in CMF with 2·50 mg/ml.	,,	,,	Partial dissociation (fragments and cells)
Trypsin 5·0 mg/ml. in CMF with 1·25 mg/ml.	,,	,,	Partial dissociation (small fragments and cells)
Trypsin 5·0 mg/ml. in CMF with 0·63 mg/ml.	,,	,,	Complete dissociation (a few small fragments)
Trypsin 5·0 mg/ml. in CMF with 0·32 mg/ml.	,,	,,	Complete dissociation

Tissue treated with 5·0 mg/ml. trypsin was readily dispersible into single cells. The dissociating effect of trypsin was completely abolished both by the soybean and by the ovomucoid inhibitor at concentrations of 15·0, 10·0 and 5·0 mg/ml.; the lowest of these concentrations is in the range of equimolarity with the concentration of trypsin. Tissues incubated in trypsin with progressively lower concentrations of the inhibitors yielded increasingly larger numbers of free cells and, finally, suspensions of single cells were obtained (Table 1). Thus, at concentrations of inhibitor that would be expected to inactivate all the trypsin in the test medium, the tissue-dissociating effect of the enzyme was wholly abolished; at lower inhibitor concentrations, and correspondingly higher amounts of active trypsin, partial and complete dissociations were obtained.

The results demonstrate that the natural trypsin inhibitors tested in this work abolish the cell-dissociating activity of the enzyme. This accords with the reported absence of cell-separating activity in DFP-inactivated trypsin[2]. While the exact mode of inactivation of trypsin by various inhibitors is not completely clear, there is good evidence that they combine with the enzyme at, or near, its active site[6,7]. It may thus be inferred that the characteristic enzymatic properties of trypsin are causally related to its cell-dissociating effect and, therefore, that degradation of a trypsin-sensitive substrate is involved in the separation of cells by trypsin. This concurs with assumptions on the role of such substrates in

the mutual attachment of cells in tissues susceptible to dissociation with trypsin.

Differences in the Disposition of Endogenous and Exogenous Substances by Cells

During recent years, evidence has been accumulating that cells often may discriminate between a substance that they synthesize and the same substance that is preformed and assimilated from the environment. This capacity to respond differently to a compound introduced from the extracellular fluid, as compared to that formed within the cell, may be attributable to the compartmentation of intracellular events.

In culture, neoplastic mast cells of the mouse synthesize histamine and 5-hydroxytryptamine and also concentrate these amines from the medium[1]. The endogenous and exogenous amines, neither of which is catabolized, are eliminated from the cell at markedly different rates[2]. It is known that the major portion of the endogenous amines in these cells is found in particulate material[3]. Density-gradient centrifugation in sucrose of homogenates of these cells grown in a medium containing radioactive histamine or radioactive 5-hydroxytryptamine showed that these labelled, exogenous amines are found in fractions sedimenting at different densities from the particulate fractions containing the endogenous amines[3]. The different compartments for the endogenous and exogenous amines can explain the differences in their rates of elimination from the cell.

The separation of the endogenous and exogenous pools of amines in these cells is not complete, however, for the exogenous amines have access to the endogenous pool. In cells with no detectable levels of endogenous histamine and 5-hydroxytryptamine, the exogenous amines are localized in sub-cellular fractions which normally contain the endogenous amines[3]. The extent to which the exogenous amines enter the endogenous compartment is a function of the levels of endogenous amines already present in that pool. These observations are in accord with the idea that the binding sites for endogenous amines, when not occupied by these amines, are accessible to exogenous amines[3].

The implications of these experiments probably are not restricted to neoplastic mast cells, nor are they likely to be limited to an explanation of the kinetics of an eliminative process. In intact brain[4] and in lung minces[5], endogenous and exogenous histamine are methylated at different rates. An obvious, though not inevitable, implication of these observations is that the endogenously formed histamine is held in a cellular compartment that is not readily accessible to the methylating enzyme. In brain[6] and in lung[7,8] endogenous histamine is found in particulate material, whereas the methylating enzyme is found in the soluble cytoplasm[9]. It is suggested that the exogenous histamine may not be bound within particles but instead is held in the clear cytoplasm, accessible to the methylating enzyme.

It should be noted that these experiments on the methylation of histamine were carried out on lung minces and intact brain, in both of which cellular integrity is preserved. Other experiments have shown that the organization of the cell must be retained to reveal the true kinetics of histamine-methylation. *In vivo*, male rats have a greater capacity to methylate histamine than do female rats[10]. This difference is manifest by kidney minces[10] and slices[11], but not by kidney homogenates[12]. In the intact cell, a rate-limiting reaction may exist that is not apparent in homogenized cells.

Conversely, conditions that may appear to be rate-limiting *in vitro* may not obtain within the intact cell. Intact muscle continues to phosphorylate glucose in the presence of an intracellular concentration of glucose-6-phosphate that, *in vitro*, would inhibit almost completely the hexokinase present in the muscle[13]. A possible explanation for this paradox is that only a portion of the glucose-6-phosphate in the cell is in contact with hexokinase.

Endogenous and exogenous amino-acids also differ in their metabolism. In yeast (*Candida utilis*)[14], fructose serves as a precursor of amino-acids, which are incorporated into protein. The yeast also concentrates from the medium exogenous amino-acids, which also are incorporated into protein. Although the amino-acids which the cell takes up exchange with the amino-acids in the medium, amino-acids synthesized from fructose do not exchange with amino-acids in the medium. Furthermore, the performed acid-soluble amino-acids in the cell are extractable with distilled water, which does not extract the endogenously formed acid-soluble amino-acids. Thus, in this yeast, exogenous amino-acids are held in a pool which is distinct from that containing endogenous amino-acids. The endogenously produced amino-acids are preferentially incorporated into protein, perhaps because the enzymes forming the endogenous amino-acids are in more favourable juxtaposition with the components involved in protein synthesis.

In neoplastic mast cells in culture, endogenous 5-hydroxytryptophan is more rapidly decarboxylated than is exogenous 5-hydroxytryptophan[2]. The more rapid decarboxylation of endogenous 5-hydroxytryptophan may indicate that it is present in a compartment more readily accessible to the decarboxylating enzyme.

The existence of different pools for endogenous and exogenous purines and pyrimidines also may be inferred. In *Bacillus cereus*, chloramphenicol appears to inhibit the incorporation into nucleic acid of adenylate arising from exogenous purines without inhibiting the incorporation of adenylate arising from the synthesis of purines *de novo*[15]. Similar findings have been obtained in investigations of Ehrlich ascites carcinoma cells with ethidium bromide[16]. In a uracil-dependent mutant of *E. coli*, exogenous deoxycytidine serves as a precursor of all the pyrimidines of nucleic acids, whereas the deoxycytidine produced from deoxycytidylate in the medium is found only in the thymine of deoxyribonucleic acid[17].

Even cell-free systems may discriminate between endogenous and exogenous substances. Particulate fractions prepared from bacteria incorporate amino-acids into protein, making use, as a source of energy, of adenosine triphosphate (ATP) produced by oxidative phosphorylation in these particles; this endogenous source of ATP could not be replaced by exogenous ATP[18,19]. In homogenates of pigeon-breast muscle, synthesis of glycogen depended on the ATP generated by oxidative phosphorylation, but was not supported by exogenous ATP or by an added ATP-generating system[20]. It would appear that a close structural relationship must exist between the ATP-synthesizing system and the ATP-requiring reaction.

Implicit in these observations on intact cells and subcellular systems is the importance of intracellular localization and the contiguity of sub-cellular substances and enzyme systems in the control of cellular events. But more specific conclusions emerge from the foregoing examples, although other conclusions may not hold for all substances in all systems. First, the turnover rate of a substance—whether it is catabolized, using in a synthetic

process, or eliminated unchanged by the cell—depends on whether it is of endogenous or exogenous origin. Second, some of the effects of drugs on intermediary metabolism differ if the metabolite is of endogenous or exogenous origin. Third, the disposition of substances of exogenous origin is governed by the intracellular concentration (the steady-state level) of the same endogenous substance, in part because of limited and relative accessibility to an intracellular compartment. Fourth, the disposition of an exogenous substance is altered as its concentration increases, not only because of limited activity of an enzyme system, but also because of limited capacity of a cellular compartment to accommodate the substance.

Effects of Alloxan Diabetes and Adrenaline on Concentrations of Free Fatty Acids in Rat Heart and Diaphragm Muscles

In alloxan diabetes rates of glucose phosphorylation, glycolysis and pyruvate oxidation in rat heart and diaphragm muscles are subnormal, and evidence has been presented that these changes in carbohydrate metabolism are due to greater availability of fatty acids for oxidation in muscle in diabetes[1,2]. The evidence was that changes in carbohydrate metabolism, similar to those seen in muscle in diabetes, could be induced in normal muscle by *in vitro* addition of fatty acids[2]; and that measurements of glycerol output by rat heart and diaphragm muscles *in vitro* suggested that the breakdown of glycerides to free fatty acids and glycerol in muscle from diabetic rats was accelerated[2,3]. We have now sought to obtain more direct evidence for this idea by measuring the concentration of free fatty acids in these muscles.

Estimates of the free fatty acid concentration in muscle are few[4,5] and have been considered unreliable[6]. Difficulties in making such estimates include breakdown of lipids during extraction of free fatty acids[7]; limited sensitivity of microtitration methods of free fatty acid[8]; and interference by phospholipids in both titrimetric methods[8] and those spectrophotometric methods based on the solubility of the copper salts of free fatty acids in organic solvents[9]. With these points in mind we have estimated free fatty acid concentrations in muscle as follows.

Alloxan diabetes was induced in rats by injection of alloxan (60 mg/kg) into a tail vein under ether anæsthesia; the animals were used 48 h later. Diaphragms (from female albino Wistar rats of 150–200 g) were incubated for 60 min, and hearts (from male albino Wistar rats of 200–260 g) were perfused for 15 min (by drip through) by techniques described in detail elsewhere[10,11]. At the end of incubation or perfusion the tissues were frozen in acetone solid carbon dioxide mixture and powdered in a percussion mortar at −70°. The powder was weighed and ground in a mortar with 5 ml. of iso-propanol/*n*-heptane sulphuric acid (40 : 10 : 1, v/v). After addition of further *n*-heptane (3 ml.) and water (3 ml.-volume of muscle water which is about 0·8 times weight of powder in g) the mixture was ground once more, the upper phase (heptane phase) separated by centrifugation and 3 ml. taken and dried at 37° under a stream of nitrogen. The lipid residue was then subjected to thin layer chromatography on silica gel 'G' (Merck) as described by Malins and Mangold[12] but using the solvent system *n*-hexane/di-ethyl ether/methanol/acetic acid (90 : 20 : 2 : 3, v/v)[13]. Desaga apparatus for thin layer chromatography was obtained through CamLab (Glass), Ltd., Cambridge. Lipids were detected by their fluorescence in ultra-violet light (258 mμ) after spraying with an ethanolic solution of 2′,7′-dichlorofluorescein, 0·2 g/100 ml. The R_F values of the separated classes were phospholipids 0·00; cholesterol 0·20; diglycerides 0·25; free fatty acids 0·3–0·4; triglycerides 0·55–0·75 and cholesterol esters 0·80–0·90. The free fatty acid zone was scraped off the plate, shaken with 7 ml. of chloroform and the supernatant separated by centrifugation. Free fatty acids were assayed spectrophotometrically at 440 mμ in a Beckman *DU* spectrophotometer on 5 ml. of the supernatant by the method of Duncombe[9]. Recoveries of palmitic, oleic and linoleic acids (0·025–0·2 μmole) added to muscle powder were in the range 90–100 per cent. The advantages of the procedure described include the short time required for extraction, specificity due to separation of free fatty acids from phospholipids and sensitivity to 0·01 μmole fatty acids.

The concentration of free fatty acid in diaphragms from fed rats incubated for 1 h in medium containing glucose (1·5 mg/ml.) and insulin (0·1 unit/ml.) was 156 ± 15 (6) (mμmoles free fatty acid/g of wet muscle; mean ± *S.E.*; number of observations in parentheses). The concentration of free fatty acid was increased in diaphragms from diabetic rats to 450 ± 64 (6); but in hypophysectomized rats the concentration of free fatty acids in diaphragm was not increased by the induction of alloxan diabetes (hypox 200 ± 26 (6); hypox diabetic 150 ± 18 (6)). When insulin and glucose were omitted from the incubation medium, the concentration of free fatty acids in diaphragm from fed rats was increased (from 156 ± 15 (6) to 370 ± 60 (6)). Under these conditions the concentration of free fatty acids was increased to 620 ± 70 (6) in diaphragms from alloxan diabetic rats. The addition of adrenaline (20 μg/ml.) to medium lacking glucose or insulin increased the concentration of free fatty acids in diaphragms from rats starved 48 h from 380 ± 40 (6) to 700 ± 50 (6), but did not significantly increase the concentration in diaphragms from fed rats (370 ± 60 (6) to 420 ± 25 (6)).

The concentration of free fatty acids in hearts from fed rats perfused for 15 min with medium containing glucose (1 mg/ml.) and insulin (0·1 unit/ml.) was lower than that of diaphragm, being 45 ± 5 (24) mμmoles/g of wet muscle. The concentration of free fatty acids was increased in alloxan diabetes to 103 ± 18 (6); and by omission of glucose and insulin to 63 ± 7 (6).

The present investigations have shown that the concentration of free fatty acids in rat heart and diaphragm

muscles perfused or incubated with medium containing glucose and insulin is increased by the induction of alloxan diabetes in normal but not in hypophysectomized rats. Moreover, they show that the concentration of free fatty acids in these muscles is diminished by the presence of glucose and insulin in the medium and may be increased in diaphragm muscle by adrenaline *in vitro*. These findings provide more direct evidence for the ideas[2] that abnormalities of glucose phosphorylation, glycolysis and pyruvate oxidation in muscles of diabetic rats are secondary to greater availability of fatty acids for oxidation; that adrenaline can accelerate breakdown of glycerides to fatty acids and glycerol in muscle; and that glucose and insulin can promote esterification of free fatty acids in muscle.

We thank the British Diabetic Association and the British Insulin Manufacturers for contributing to the cost of these investigations. We also thank Prof. F. G. Young for his encouragement.

Biosynthesis of Sucrose with Sugar Cane Leaf Preparations

On the basis of results from photosynthetic experiments with $^{14}CO_2$, Buchanan *et al.*[1] first suggested that uridine diphosphate D-glucose (UDPG) is the immediate precursor of sucrose in green plants. Later, Leloir and co-workers[2] and others[3] demonstrated that extracts from wheat germ, peas, sugar beets, and other plants contain enzymes capable of catalysing the synthesis of sucrose from UDP-D-glucose by two similar reactions:

UDP-D-glucose + D-fructose ⇄ sucrose + UDP

UDP-D-glucose + D-fructose 6-phosphate ⇄ sucrose phosphate + UDP

In these reactions the equilibrium lies in the direction of sucrose or sucrose phosphate formation[3]. It was also shown that wheat germ contains a phosphatase capable of converting the sucrose phosphate to sucrose. The relative importance of the two mechanisms of sucrose synthesis in plants is not clear at present.

Pandya and Ramakrishnan[4], and Shukla and Prabhu[5] reported the presence of a sucrose phosphorylase in sugar cane plants which is similar to that found in the micro-organism *Pseudomonas saccharophila*[6]. According to these authors, the synthesis of sucrose in sugar cane occurs by the reaction:

α-D-glucose 1-phosphate + D-fructose ⇄ sucrose + inorganic phosphate

In the past, various attempts in this and several other laboratories to obtain a preparation from sugar beets, peas, carrots, and other plants that would utilize α-D-glucose 1-phosphate as a donor for the D-glucose moiety for *in vitro* biosynthesis of sucrose met with failure. Turner[7] in 1953 reported the synthesis of sucrose from these substrates with a preparation from peas when a yeast extract was added to the reaction mixture. However, he[8] afterwards found that sucrose was synthesized from UDP-D-glucose and D-fructose as previously demonstrated by Cardini *et al.*[2]. Turner[8] attributed sucrose formation in earlier experiments to the presence of UDP-D-glucose in the yeast juice added to the reaction mixture.

Shukla and Prabhu[5] reported that the main difference in the sucrose phosphorylase of sugar cane and of *Pseudomonas saccharophila* is that the equilibrium constant of the bacterial enzyme reaction is 0·058; whereas the K of the sugar cane reaction is 5·6. This equilibrium constant is clearly inconsistent with that of the sucrose phosphorylase reaction.

In view of these facts, we decided to re-examine the *in vitro* biosynthesis of sucrose with enzyme preparations from sugar cane leaves. Results of a preliminary investigation on this subject are reported in this communication.

We were unable to confirm the results of Pandya and Ramakrishnan[4] and Shukla and Prabhu[5] that sugar cane contains a sucrose phosphorylase capable of synthesizing sucrose from α-D-glucose 1-phosphate and D-fructose or D-fructose 6-phosphate. Consistent with the results of previous investigations[2,3] on other plants, the only sucrose synthesizing enzyme that could be demonstrated in sugar cane extracts was a transglycosylase that transfers the D-glucose moiety from UDP-D-glucose to D-fructose to form the disaccharide.

Approximately 50 g of immature sugar cane leaves were homogenized in a Waring Blender, the homogenate was centrifuged at 10,000*g* for 10 min, and the supernatant solution was fractionated with saturated ammonium sulphate at *p*H 7·0. The precipitate obtained at 30–60 per cent saturation was dissolved in water and the solution dialysed overnight against 0·05 M *tris* buffer, *p*H 7. This enzymatic preparation (5 ml.) was used in the sucrose synthesis experiments.

The reaction mixture contained 0·5 μmole of ATP, 0·25 μmole magnesium chloride, 2·5 μmoles phosphate buffer, *p*H 6·7, 0·5 μmole D-fructose or D-fructose 6-phosphate, $6·7 \times 10^{-4}$ μmole (0·025 μc.) UDP-D-[^{14}C] glucose, or $1·6 \times 10^{-3}$ μmole (0·06 μc.) D-[^{14}C] glucose 1-phosphate, and 20 μl. of the enzyme preparation in a total volume of 45 μl. The mixture was incubated for 60 min at 37° C and then subjected to electrophoresis on acid-washed paper (Whatman No. 1) in 0·2 M ammonium formate buffer, *p*H 3·7.

The non-mobile radioactive compounds were eluted from the paper, and the eluate was passed through a mixed 'Amberlite *MB*3' resin (H^+, OH^-) form. The eluate containing the radioactive compounds was mixed with 1 μmole of non-radioactive sucrose and chromatographed with butanol/pyridine/water (6: 4: 3 v/v). Radioactivity on the chromatograms was detected by exposure of the paper to X-ray film (Kodak-'No screen'). The unlabelled sugars were detected on the paper chromatograms with silver nitrate reagent[9]. The enzymatically synthesized radioactive compound from UDP-D-[^{14}C] glucose and D-fructose was found to co-chromatograph with authentic sucrose. The radioactive spot was eluted and hydrolysed with invertase. Subsequent chromatographic separation of the products revealed that the radioactivity resided in the glucose moiety. The recovery of activity of carbon-14 in the sucrose amounted to 68 per cent of the UDP-D-[^{14}C] glucose used as substrate.

Sucrose labelled with carbon-14 was formed only when UDP-D-[^{14}C] glucose and D-fructose were incubated with the enzyme. When D-[^{14}C] glucose 1-phosphate was substituted for UDP-D-[^{14}C] glucose in the reaction, sucrose could not be detected; nor was radioactive sucrose or sucrose 6-phosphate synthesized when D-fructose 6-phosphate was used as the D-glucosyl acceptor in the reaction with D-[^{14}C] glucose 1-phosphate.

In another experiment with sugar cane leaves, the leaf extract was separated with ammonium sulphate into three fractions of 0–30 per cent, 30–60 per cent, and 60–75 per cent saturation. When these preparations were used as a source of enzyme for the synthesis of sucrose, it was found that only the 30–60 per cent fraction was effective in synthesizing sucrose from ^{14}C-labelled UDP-D-glucose and D-fructose. As in the previous experiment, sucrose was not formed when ^{14}C-labelled D-glucose 1-phosphate was substituted for radioactive UDP-D-glucose in the reaction. The other ammonium sulphate fractions were ineffective for the synthesis of sucrose from ^{14}C-labelled UDP-D-glucose and D-fructose or D-fructose 6-phosphate; or from ^{14}C-labelled D-glucose 1-phosphate and the same D-glucose acceptors.

When sugar cane chloroplasts were used as an enzyme source, sucrose was synthesized from ^{14}C-labelled UDP-D-glucose and D-fructose or D-fructose 6-phosphate to about the same extent as with the 30–60 per cent ammonium sulphate fraction (approximately 65 per cent). However, although D-fructose 6-phosphate could serve as a glucose acceptor, no sucrose phosphate could be detected. It appears that a phosphatase is present in the chloroplasts that either hydrolyses the enzymatically synthesized sucrose phosphate or hydrolyses the D-fructose 6-phosphate to D-fructose, which then serves as an acceptor for the glucose of the sugar nucleotide.

We thank Mr. Kenyon D. Beatty, research agronomist, of the Southwestern Irrigation Field Station, U.S. Department of Agriculture, Brawley, California, for supplying the sugar cane leaves.

A Non-enzymatic Oxidative Degradation of Cellulose occurring in Preserved Cabbage Tissue

IT is recognized that plant materials preserved in dilute acetic acid exhibit a slow loss of tissue strength as a result of the structural components undergoing hydrolysis. This is caused either directly by the low *p*H of the medium, or indirectly from the presence of hydrolytic enzymes secreted by micro-organisms previously associated with the tissue[1]. An additional form of tissue breakdown, which has not apparently attracted previous attention, has been observed in the work recorded here. This is in no way connected with microbial action, and is oxidative in character.

This form of softening is, in fact, to be seen to a small extent in many chemically- and heat-preserved fruits and vegetables; but in the case of red cabbage—shredded and preserved in acetic acid—deterioration is rapid and storage for three weeks at 30° C is sufficient to bring about a radical change in the texture of the shreds. The essential role of oxygen in this breakdown is apparent from the fact that when shredded cabbage in acetic acid (*p*H 3·25) is placed in a loosely sealed container, it is the uppermost shreds which are the first to soften. Furthermore, hermetically sealing the container under vacuum prevents this from occurring.

In order to obtain some indication of the nature of the softening reaction, the effect of adding a number of substances to shredded red cabbage in acetic acid (*p*H 3·25) under aerobic conditions was observed. Certain substances were found to inhibit or retard softening. These could be classified as follows: the strong reducing agent sulphur dioxide which had a marked effect even at a concentration of 100 p.p.m.; the oxidizing agent iodine; sequestering agents such as ethylenediamine tetraacetic acid and pyrophosphates; and general precipitating agents such as alcohol, formaldehyde and phosphomolybdic acid. None of these results is inconsistent with the oxidation of pectin and cellulose by ascorbic acid investigated by Deuel[2]. Pasteurization, so that the shreds were held at a temperature of 82° C for 20 min, failed to reduce softening, thus suggesting that the reaction was non-enzymatic.

Analysis of the total pectic substances in softened and crisp shreds of the same age, taken respectively from the upper- and lower-most regions of containers over a period of time, indicated that softening was accompanied by a loss of pectic substances in the tissue (Table 1). A rise in the pectic content of the liquid contents, approximately equivalent by weight to that lost by the softened shreds, also occurred.

Table 1

Days' storage at 30° C	Percentage total pectic substances (as calcium pectate)		
	Topmost shreds	Bottommost shreds	Liquor
3	0·66	0·70	0·018
17	0·63	0·70	0·034
31	0·49	0·74	0·034
45	0·50	0·70	0·040
62	0·47	0·70	0·042

Estimation of the crude fibre content, as an indication of cellulose content, of soft and crisp shreds showed a loss of cellulose from the former. The means of the results from 7 identical containers were 0·84 per cent and 1·17 per cent respectively, the difference being statistically significant at the level $P = 0{\cdot}02$ approximately.

Using methods based on the assay of polygalacturonases[3], and also a method involving the measurement of the strength of pectic acid–aqueous cabbage extract gels (*p*H 3·5), no evidence was obtained that water-soluble constituents of cabbage were capable of degrading pectic acid appreciably in the presence of oxygen over a period of several weeks at 30° C.

Utilizing sodium carboxymethylcellulose as a substrate, as in the assay of cellulolytic enzymes[4], but using a Ferranti viscometer, it was found that red cabbage extract brought about a marked reduction in the viscosity of solutions of this cellulose derivative. Oxygen was essential for the reaction to proceed, anaerobic conditions resulting in its complete cessation. In Table 2 figures are given relating to the apparent viscosity of a 1·5 per cent solution of sodium carboxymethylcellulose in 3 per cent acetic acid (*p*H 3·6), containing 50 per cent aqueous cabbage extract, stored at 30° C over a period of time.

Table 2

Days' storage at 30° C	Apparent viscosity in centipoises	
	Aerobic conditions	Anaerobic conditions
0	37·0	37·0
6	25·0	35·0
13	19·5	35·0
27	14·5	35·0
42	10·5	34·0
69	6·0	33·0

Subsequent tests showed that the foregoing reaction was inhibited by the same substances as prevented the softening of shredded cabbage in acetic acid and that boiling the cabbage extract prior to its use, to inactivate any enzymes present, had no effect on the rate of the reaction.

It is concluded from this initial investigation that a factor exists in red cabbage which is non-enzymatic and which is capable of directly or indirectly carrying out an oxidative degradation of cellulose *in situ* under acid conditions. The change of protopectin to soluble pectin which apparently accompanies the loss of cellulose from the tissue could be explained either on the assumption of a similar oxidative factor affecting protopectin but not pectin, or alternatively that the insolubility of the protopectin present derived from its association with cellulose, a hypothesis most recently reviewed by Joslyn[5].

PHYSIOLOGY

Reducing Agents and Absorption of Iron

Iron absorption has been shown to be increased by a variety of substances. Ascorbic acid is perhaps the best known of these[1]. The activities of inosine[2], succinic acid[3], fructose[4] and cysteine[5,6] have been discovered more recently. Several different hypotheses have been offered in explanation of the action of these substances. (1) That ferrous iron is more readily absorbed than ferric iron and that the ferrous form is maintained by an intra-luminal intestinal reducing agent (ascorbic acid); (2) that iron transport is linked with oxidative metabolism (succinic acid); (3) that iron transport depends on a carrier or chelating agent (fructose, cysteine).

It has not been generally appreciated that all these substances are reducing agents, either of themselves or in the milieu of the cell's interior. Succinic acid can reduce the prosthetic group of succinic dehydrogenase; fructose can reduce DPN when it enters glycolysis as glyceraldehyde-3-phosphate; inosine can reduce the prosthetic group of xanthine oxidase. All these substances can change the redox balance of the absorbing cell. A common action is also suggested by the quantitatively similar effect each exerts on iron absorption, a 1·5–2-fold increase.

We suggested that when the redox balance within the absorptive epithelium is tipped in the direction of reduction, iron absorption is increased. As a preliminary test of this hypothesis we administered by mouth iron plus hydroquinone, a reducing agent without known or postulated metabolic function. Iron absorption was examined in Walter Reed strain rats, weighing 250–400 g, utilizing repeated total-body counting to estimate absorption[7]. Control rats were dosed with 250 μg of iron as ferric chloride with iron-59 as tracer and with 1·6 mg of ascorbic acid, all dissolved in 1 ml. of distilled water. Experimental rats were dosed with the identical solution except for the addition of hydroquinone in varying doses. The small excess of ascorbic acid was included to preserve the ferrous state of intraduodenal iron in both control and experimental groups so that differential formation and absorption of ferric iron would not be in question.

Table 1. Iron Absorption in Control and Experimental Rats

Group	No. of rats	Hydroquinone dose (mg)	Percentage absorption (mean)
I	8	25	21·0
I (control)	8		12·7
II	8	45	21·0
II (control)	10		13·8

Absorption was increased in the hydroquinone-dosed rats (Table 1). The different doses of hydroquinone were similar in their effects on iron absorption. A *t*-test comparison between the combined hydroquinone-dosed rats and the controls showed the difference to be significant, with $P < 0{\cdot}005$. Separate experiments showed that the ascorbic acid used was sufficient to maintain the ferrous state of intraduodenal iron for at least 2 h. Hydroquinone, if it indeed functions as a reducing agent in increasing iron absorption, appears to work within the absorbing cell.

The 50 per cent increase in iron absorption obtained with hydroquinone is similar to that obtained with other compounds. This increase is relatively small compared with the increase which may occur with iron deficiency. The role which the intracellular redox potential may play in the absorption of iron in normal and abnormal states requires further definition.

We thank Dr. Pearl Anderson and Mr. Harold Williams for advice and assistance.

A Theoretical Model for the Computation of Decompression Tables for Divers

Discussions on the mechanism of decompression sickness have been focused mainly on the saturation and desaturation of the tissues with inert gases. To assess the capacity of the organism to free itself of an abundance of inert gas, experimental methods have usually been applied. Thus it has been possible to define a limited number of nitrogen-elimination rates which are spoken of as representing different types of tissues. Such information is, however, of limited value for the estimation of the relative importance of a certain tissue fraction (in terms of half-saturation time) for the genesis of decompression sickness. In measurements of nitrogen elimination the volumetrically large tissue fractions dominate the picture in a degree which is not necessarily related to their importance as bends tissue.

The conception of different histological types of tissues as representing different elimination rates is an oversimplification. Obviously, cells which are located at a larger distance from capillaries in a tissue will have slower nitrogen-elimination rates than those close to the walls of perfused vessels.

A more fruitful approach to the problems of inert-gas exchange in the organism seems to be to consider the body as composed of an unlimited or very large number of fractions as regards nitrogen-elimination rates. The ex-

tremes of such a spectrum of fractions would be one representing some imaginary cells with an infinitely rapid elimination rate and another representing cells with an extremely slow elimination rate. Neither of these extremes would present problems as bends tissue after a period of increased pressure followed by decompression, whereas it is possible to conceive of a fraction somewhere between them which would have critical over-saturation with inert gas.

A mathematical model has been devised which makes it possible to apply the concept of a great number of rates of gas exchange in the body to evaluate different programmes for pressure exposure. With this model it is possible to take into consideration different times of exposure and varying pressures and solubility of different breathing gases. For practical reasons, however, it must be presupposed that the gas-exchange rate of a certain tissue fraction is constant.

The possibility of symptom-producing changes in a certain tissue fraction is assumed to be related to the following main factors: (1) inert gas tension in relation to surrounding pressure (oversaturation ratio); (2) the magnitude of surrounding pressure; (3) the time that oversaturation exists.

In covariation with these factors there are probably others, for example, amount of dissolved gas, susceptibility of the tissue to deformation, and diffusion rate of different gases. Consequently a theoretical investigation of the connexion between each of the above-mentioned factors separately and the risk of decompression sickness is of little practical value.

However, to make possible a rational experimental investigation of what over-saturation ratios are acceptable under different conditions and in different tissues, it is necessary to be able to calculate the optimal decompression programme which fits in with the criterion (the over-saturation ratio, etc.) to be tested. The optimal decompression programme would then be the one in which the chosen criterion exists all the time in at least one tissue fraction, without being exceeded.

Mathematical considerations. The well-known exponential equation for the equilibration of differences in gas tensions between a tissue and breathing gases at constant external pressure has been modified (see footnote) to be valid for varying external pressure.

As the mathematical model is adopted for use with several breathing gases, the different tissue fractions are characterized not only by the elimination constant (k) (for explanation of symbols, see footnote) of one gas but also by its relation to the constants of the other gases. By application of the above-mentioned equation the tension of each gas is calculated, after which the total gas tension of each tissue fraction can be obtained by summation. To allow the factor of external pressure change ($U+H$) to be considered as linear, the course of the pressure programme must be split into sufficiently short time intervals. For each interval the following factors must be defined: the time of the beginning of the interval (t_0), external pressure at the beginning of the interval (a), external pressure change (b) per time unit within the time-interval, relative partial pressure of each breathing gas in the time interval (U_1, U_2, etc.). It should be noted that the value of the gas tension at the end of an interval constitutes the initial gas tension (P_0) of the next interval. When the aforementioned parameters which are valid for a dive are applied in the calculations, the over-saturation ratios for any tissue fraction at all intervals can be tabulated.

When an optimal decompression programme is to be determined, the maximal ascent (b) per time unit for each time-interval and tissue fraction which fits in with the chosen criterion is calculated. The computation technique calls for iterative calculation of the ascent which can be allowed within the time-interval, as the change in pressure modifies the conditions for gas exchange in the tissue. The tissue fraction in which the criterion is reached with the smallest ascent limits the decompression that is tolerable during the interval. The programme for the diver's ascent from the dive is obtained when the calculations have been performed and tabulated for all the time intervals of the dive.

The need to make the calculations, some of which have to be iterated, for a great number of tissue fractions and time-intervals makes the use of an electronic computer necessary if a series of any practical importance is to be worked through.

A number of combinations of different criteria are now under computation according to the rules given here with the view of their being subjected to experimental testing.

$$P = UH - \frac{Ub}{k} + \left(P_0 - Ua + \frac{Ub}{k}\right) \exp - k\,(t - t_0)$$

P, pressure of gas dissolved in tissue fraction at time t; U, fraction of pressure exerted by component of gas mixture in the lungs; H, external pressure at time t. $H = a + b\,(t - t_0)$; a, external pressure at time t_0; b, external pressure change per time unit; P_0, pressure of gas in tissue fraction at time t_0; t time variable; t_0, initial value for t; k, elimination constant.

Changes in the Motor Neurones after administering Muscle Relaxant and Convulsant Drugs

Mature female rats were given 2 mg of the muscle relaxant 'Flaxedil' (gallamine triethiodide) repeated at intervals of 24 h for three days with full clinical recovery between doses. The animals were killed with chloroform 72 h after the last injection of 'Flaxedil' and the tissues fixed by perfusion of 10 per cent formalin and 5 per cent acetic acid via the aorta. The cervical and lumbar enlargements of the spinal cord were sectioned at 7μ and stained with 0·5 per cent aqueous cresyl violet to show the Nissl substance in the anterior horn nerve cells. Only the large anterior horn cells were included in the investigation.

Morphological changes, similar to those produced by section of the axon or prolonged electrical stimulation of a nerve[1], can be demonstrated in most of the anterior horn cells of the spinal enlargements within three days of the last injection of 'Flaxedil'; cytoplasmic and nuclear swelling and early chromatolysis could be easily identified (Fig. 1*a*) but have not yet been traced beyond the three-day stage.

Treatment of a second series of rats with convulsant doses of strychnine and cardiazole produces similar chromatolytic changes in these somatic efferent neurones (Fig. 1*b*).

These observations may be of interest and value to the neurophysiologist in the assessment of the function of the nerve cell and in explaining the mystery of its abundant chromidial (Nissl) substance and its role in nerve impulse transmission.

After crushing the hypoglossal nerve, Brattgard, Edstrom and Hyden[2] investigated the chemical changes occurring in the individual nerve cells of the hypoglossal nucleus during the so-called retrograde degeneration or, more properly, retrograde reaction. Between the second and eighth day following the operation, the main features are an increase in cell volume, maintenance of the total RNA content per cell, and an increase in proteins and lipids. The visible change in the Nissl substance they regard as a transition from an active to a more active form of RNA and not as a reduction in its amount.

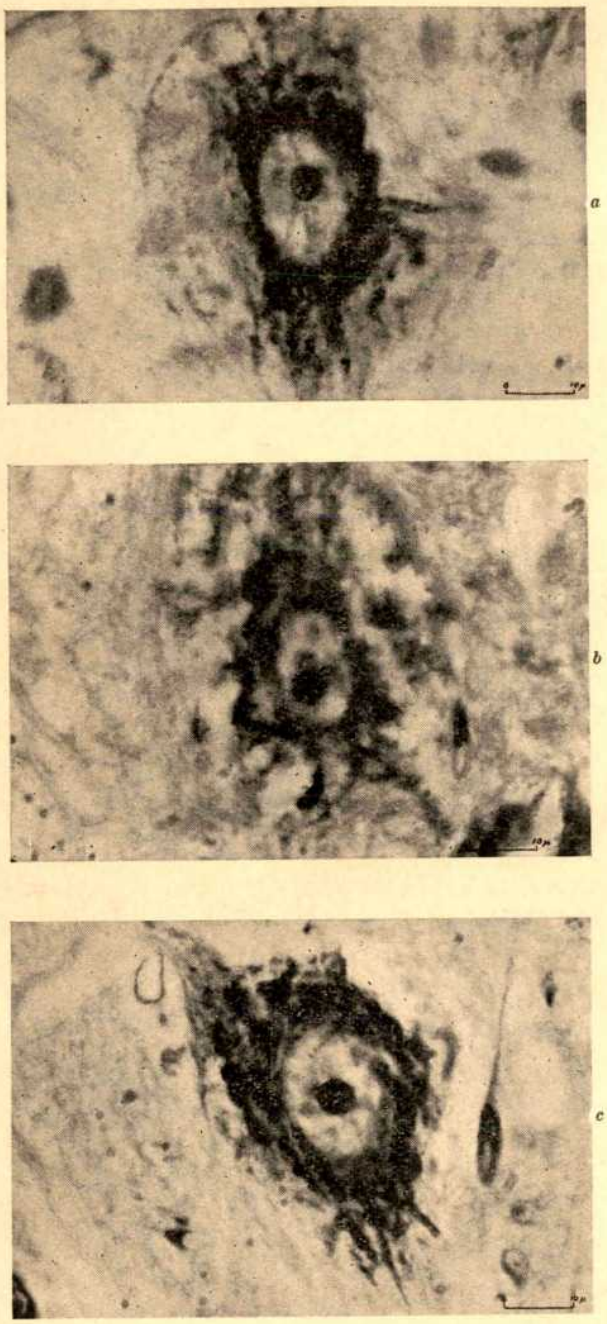

Fig. 1. Anterior horn nerve cells of the rat spinal cord stained with cresyl violet. *a*, 72 h after the last of three injections of 'Flaxedil'; *b*, 72 h after the last of three injections of strychnine; *c*, normal anterior horn nerve cell

The origin of synaptic vesicles, which are believed to carry the chemical transmitter at the synapse, has been investigated by Van Breemen, Anderson and Reger[3]. These authors suggest that the vesicles, originating from the Golgi complex (smooth-membraned vesicles) in the cell body, migrate through the axoplasm to reach the synapse. It may be, then, that in normal circumstances the ribonucleoprotein (chromidial substance) produces a secretion and thereafter the Golgi complex stores and transmits the secreted material in the synaptic vesicles along the axoplasm to the nerve ending.

Brattgard *et al.*[2] associate the production of the proteins and lipids with the regeneration of the nerve and later with the maturation of the nerve. Since the same retrograde or chromatolytic reaction can be obtained by administering a drug like strychnine where there is no call for nerve regeneration, the increased activity of the RNA and other morphological features suggest increased secretion. This is also compatible with the known function of strychnine, namely, its central stimulatory action on the nervous system resulting in increased activity of the anterior horn cells. Perhaps, then, excessive activity of the nerve cell causes such accumulation of normal secretion in the cell body that it disperses or fragments the Nissl substance, giving the chromatolytic effect.

It is difficult, however, to correlate what is apparently an increased functional state of the nerve cell with the flaccidity of the musculature after administering the muscle relaxant 'Flaxedil' unless we regard the effect of the drug as a blockade of the natural chemical transmitter at the myoneural junction accompanied by persistent hypersecretion on the part of the nerve cell to overcome the blockade.

Flow of Uterine Blood, and the Œstrous Cycle

Although much has been written describing vascular changes in the endometrium with the œstrous cycle, little information is available regarding the changes in flow of blood to the whole uterus, which is largely myometrium, during this cyclic physiological event. Recently, it has been demonstrated that the fraction of an intravenously administered physiological dose of tritiated-epinephrine which is taken up from the circulation and bound in the uterus varies more than 4-fold between œstrus and dioestrus[1]. Since tritiated-epinephrine is rapidly removed from the circulation, such a change could be a consequence of an alteration in the fraction of the administered catecholamine which is delivered to this organ. Sapirstein's method[2] was used to evaluate the fraction of the cardiac output which perfuses the uterus at various times in the œstrous cycle. (The legitimacy of applying this method for determining uterine blood flow was confirmed by demonstrating that, during the first minute after injection of potassium-42, there was no dependence of uterine uptake upon time, despite continuing recirculation of the indicator[2].) It will be shown that during all phases of the œstrous cycle the uterus receives 0·2–0·3 per cent of the cardiac output.

Sprague–Dawley female rats weighing 180–200 g received 180,000 c.p.m. of potassium-42 in 0·2 ml. of normal saline within 2 h after a vaginal smear was taken for determination of the œstrous phase. The animals were beheaded 15 sec later; the uterus was then removed and weighed, and the potassium-42 present in this organ was assayed in a scintillation well counter (Nuclear, Chicago). Standard counts were made with 1 per cent of the injected potassium-42 every 15 min to correct for radiation decay. Vaginal smears were analysed according to Papanicolaou's method[3].

Although there was an increase in the weight of the uterus as rats approached œstrus, there was no corresponding increase in the proportion of the cardiac output which perfused the uterus (Table 1). Thus, if the cardiac output does not change during the œstrous cycle, the flow of blood to each unit weight of uterus actually decreases during the œstrus. More tritiated-epinephrine is bound in the uterus during œstrus[1]. Since alterations in the distribution of circulating blood cannot explain this phenomenon, it

Table 1. Effect of Œstrous Cycle on Uterine Blood Flow

	% injected ^{42}K*	Mean uterine weight	% injected ^{42}K/g
Diœstrus (12)	0·31 ± 0·05 (*S.E.*)	172	1·8 ± 0·23
Proœstrus (6)	0·30 ± 0·07	202	1·5 ± 0·27
Œstrus (6)	0·25 ± 0·05	253	1·0 ± 0·15†
Metaœstrus (6)	0·22 ± 0·06	158	1·4 ± 0·24

* Per cent injected potassium-42 is taken to represent per cent of cardiac output delivered to the uterus.
† $P < 0·02$ compared to diœstrus.

must be concluded that the mechanism for binding tritiated-epinephrine is altered during the œstrous cycle.

Investigations with oophorectomized rats have indicated that the atrophic uterus receives 0·045 per cent of the cardiac output[4]. Administration of œstrogen resulted in a 3-fold increase in this fraction. In these experiments flow of blood through the ovarian artery, which is responsible for a portion of the uterine blood flow, had been cut off. The value obtained for the fraction of the cardiac output delivered to the uterus 4 h after œstrogen administration, 0·2 per cent, is compatible with that reported here. The changes noted with œstrogen administration were in a situation of almost total œstrogen deprivation and uterine atrophy. It is evident that the changes produced in delivery of blood to the uterus by cyclic fluctuations in œstrogen-levels are not nearly as marked as those observed after œstrogen administration to oophorectomized rats.

Fœtal Myoglobin in the Urine of an Adult

A fœtal form of myoglobin has been shown in newborn animals[1] and human infants[2], and it has a different electrophoretic mobility from myoglobin in adults. This communication describes the presence of fœtal myoglobin in the urine of an adult with idiopathic myoglobinuria.

The patient was a 28-year-old female with a long history of muscle pain associated with the passage of dark urine. The diagnosis of myoglobinuria was established during an acute attack, although it was noted that her urinary myoglobin precipitated in 80 per cent saturated ammonium sulphate. Since fœtal myoglobin is not as soluble in ammonium sulphate as the adult protein[1], the presence of a fœtal form of myoglobin was suspected.

Fœtal myoglobin was prepared from psoas muscles of stillborn infants, and adult myoglobin was obtained from the psoas muscle of an adult who died of a non-myopathic disease. The muscle tissues were homogenized in the cold with distilled water and the cellular detritus centrifuged out. The two respective muscle liquors and the patient's urine were purified simultaneously by column chromatography, utilizing carboxymethylcellulose according to the method of Åkeson and Theorell[3]. Following elution from the column with phosphate buffer (*p*H 6·9), the myoglobins were reduced to the met-forms with potassium ferricyanide and then dialysed against distilled water. Electrophoresis was performed on cellulose acetate at 120 mV with barbital buffer (*p*H 8·6, ionic strength 0·1 M) for 110 min. Concurrently, samples of the patient's serum and hæmoglobin were subjected to electrophoresis. The resulting separations were stained with benzidine for iron, as well as with nigrosin for protein.

The results (Fig. 1) demonstrate the presence of a urinary iron-containing protein in the same electrophoretic region as purified fœtal myoglobin. In addition, the patient's urine had an iron-staining protein corresponding

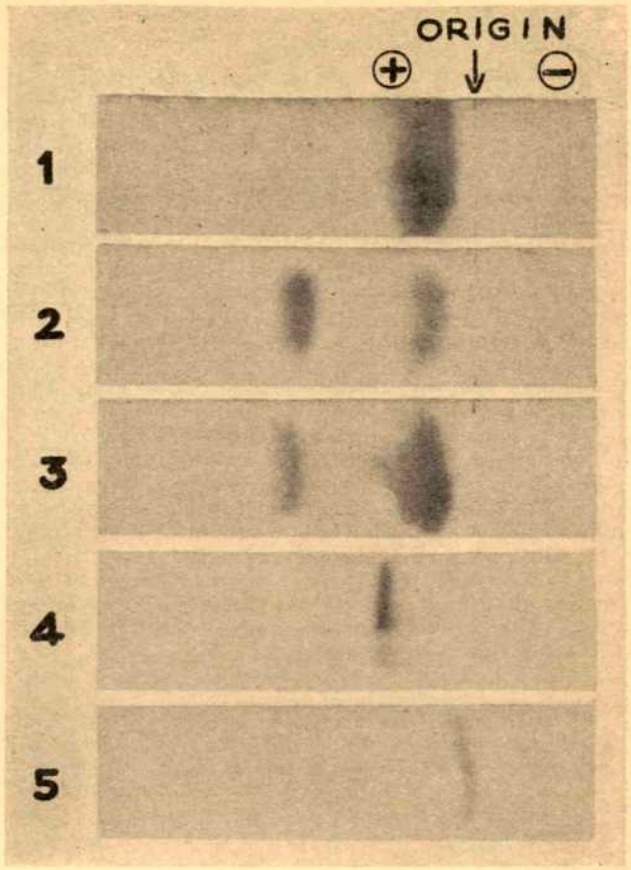

Fig. 1. Electrophoresis on cellulose acetate with barbital buffer (*p*H 8·6; 0·1 M ionic strength) and stained with benzidine. 1, Adult myoglobin; 2, fœtal myoglobin; 3, patient's urinary myoglobin; 4, patient's hæmoglobin; 5, patient's serum

in mobility to the adult myoglobin. Comparison of the stained areas by densitometry, to ascertain relative content of the two urinary proteins, showed 43 per cent fœtal and 57 per cent adult form. The serum and hæmoglobin patterns did not show iron-containing proteins in the same areas as either fœtal or adult myoglobin. The strips stained with nigrosin for protein gave the same patterns, except in the instance of the serum sample, which showed a normal pattern.

These findings indicate that during an attack of myoglobinuria this patient excreted a urinary protein which was about one-half fœtal and one-half adult myoglobin. Although muscle biopsy was not performed, it is presumed that this abnormal myoglobin originated in the patient's muscles, and that it represented persistence of the fœtal protein into adulthood. Further, it is speculated that this molecular defect may be responsible for the myoglobinuria.

Some Statistical Aspects of Blood Sugar Regulation

In the examination of physiological regulations we are often concerned with averages observed on successive occasions with short time-intervals. Other statistical parameters could be also used, since they throw some light on regulatory mechanisms. This can be shown by the following results.

Long-term reliability of fasting blood sugar-level is very low ($r = 0{\cdot}32$), but if the time elapsed between the first and the second taking of blood is short (about 1 h) correlation appears to be relatively high: $r = 0{\cdot}79$. This figure has been obtained on fasting men at rest. If before the second blood-letting they were made to walk on a tread-mill (15 min at 7 km/h), averages did not change, but the correlation between the successive blood sugar-levels determined with the same time-interval fell to 0·57. Therefore something happened which was not reflected by averages, but interfered with correlations.

If $r = 0$, blood sugar variations on successive occasions would be completely independent and no regulatory influence for a given time-interval could be supposed. If $r > 0$, it has no obvious meaning: it may be due to regulatory activity or to passive maintenance of the same blood sugar-level during a short period. But if correlations between successive occasions change in an orderly way, their variations may be meaningful.

Tables 1 and 2 show what happens with half-hourly intervals after absorption of glucose (30 g).

Table 1. Blood Sugar-levels. Adult Women, $n = 52$ (g/100 ml.)

	Arith. mean	σ	C.V.
Fasting	1·02	0·14	13·72
After glucose:			
30 min	1·47	0·26	17·68
60 min	1·39	0·28	20·14
90 min	1·13	0·22	19·46
120 min	0·97	0·13	13·40

Table 2. Correlations between Blood Sugar-levels Adult Women, $n = 52$

		1	2	3	4	5
1	Fasting	—	0·25	0·05	0·25	0·51
2	30 min		—	0·55	0·38	0·37
3	60 min			—	0·67	0·43
4	90 min				—	0·77
5	120 min					—

Half an hour after a glucose meal, blood sugar-level attains its highest average. Absolute and relative variabilities rise simultaneously and the correlation with the fasting-level appears to be very low, much lower indeed than short-term fasting reliability. After 1 h the average begins to decrease whereas both variabilities are at their peak value. Thereafter, averages and variabilities decrease simultaneously. There is an increase of 'disorder' followed by a progressive decrease.

Correlations grouped in Table 2 have two prominent features. In the upper row, correlations between fasting-level and after-glucose-levels disappear at the 60th min, then rise again, and the last figure is twice as great as the first one and is significant. On the other hand, figures in the lowest diagonal show that correlations between successive blood sugar-levels, beginning with a very low value, rise steadily and at the end we find a coefficient as high as fasting short-term reliability.

The steady increase of correlations in the lowest diagonal probably reflects the growing efficiency of regulatory process. In the upper row the disappearance of the correlation between the fasting and after-glucose level at the 60th min, followed by a remarkable rise, means that after a break there is a tendency to restore the initial fasting-level. Nevertheless, even after 2 h this result is not completely achieved: in column 5, the first figure is still lower than the last one which, as I have already pointed out, is as high as fasting reliability.

Moreover, in Table 1 the last average is lower than the first; the difference is small, but significant. A similar difference has been observed more than once, and some authors, in order to define the fall of the last observed value below the fasting-level, used words such as 'hyper-correction'. This word seems to mean that physiological regulations should in all circumstances restore a fixed 'normal' value. If for some reason they cannot 'correct', at least they must 'hypercorrect' the departure from the 'normal' point.

In accordance with some other results my figures have a less-metaphysical meaning. The comparison of averages, variabilities and correlations show that 2 h after a glucose meal a new slightly different orderliness is attained. This may be explained in many ways, which are not alternative.

The fall of blood sugar-level below the fasting value can be due to the fact that 2 h after a glucose meal the subjects are still hungry. The same fall has been observed twice in fasting men at rest as well as after a tread-mill walk (first average: 0·95 g/100 ml.; second average: 0·90). Perhaps this small difference can be explained also by psychological interferences, the first blood-letting being apparently feared more than the second or the third. If this is so, 'normal' values, usually represented by the first fasting-level, may be a little exaggerated by emotive hyperglycæmia.

We cannot standardize either laboratory animals or human subjects. Alimentary habits, activities preceding the test and possible psychological perturbations are seldom taken into account. Of course, it would be difficult to ascertain them in every case. Therefore, we are left with an unavoidable margin of uncertainty. Nevertheless, my figures agree with conclusions already suggested by the examination of intra-individual variability[1]. In fact, the living organism is never in equilibrium, but struggling for it. In continuously changing situations physiological regulations tend to maintain a limited (statistical) orderliness, not necessarily to restore the previous one.

PHARMACOLOGY

Thymectomy in Dogs with Renal Homografts treated with Drugs

Miller[1] has reported an additive effect of X-irradiation and thymectomy in depressing immunological mechanisms in adult animals. Accordingly an investigation was undertaken to determine whether thymectomy improved the functional survival of homologous renal transplants in dogs treated with drugs.

The experimental preparation and assessment of results were identical to that reported previously elsewhere[2]. Using pentobarbitone anæsthesia with air-insufflation of the lungs, the thymus was removed from mongrel dogs of either sex, via a right thoracotomy through the second inter-space. At the same time, a kidney from an unrelated dog was transplanted to the right iliac fossa and the animal's own two kidneys were removed. The drugs were administered as follows: actinomycin *C* (10 γ/kg) intravenously on the day of operation and at weekly intervals. 6-mercaptopurine suspension 5 mg/kg intramuscularly on the day of operation, followed by 'Imuran' daily by mouth, 10 mg/kg on the first and second day after operation and 5 mg/kg on subsequent days. The dose was reduced if the total white cell count fell below 5,000 cells/mm.^{3}. This drug combination has been found previously to be effective in prolonging canine renal homograft survival[2].

Table 1

Experimental groups	Total No. of animals	Animals dying with marrow depression	Animals surviving beyond 14 days and those dying before 14 days with microscopic rejection	Animals surviving beyond 20 days with good renal function	Animals dying after 14 days without microscopic rejection	Animals surviving beyond 3 months	Mean survival time
Thymectomy/actinomycin *C*/'Imuran'	8	4	7	4	1	0	17
Actinomycin *C*/'Imuran' (series II)	11	5	8	3	4	0	17

The results of the experiments are shown in Table 1, where a comparison is made with similar experiments performed without thymectomy.

The control experiments were performed concurrently in the same laboratory and have been reported elsewhere[3]. It can be seen that thymectomy has not improved the length of survival of functioning renal transplants. Examination of the thymuses of the animals treated with the thiopurine and actinomycin drug combination showed a very marked diminution in size of the organs and a severe depletion of lymphoid follicles.

In the context of these experiments it would appear that if the thymus has an important role in the rejection of canine renal transplants in adult animals, then the drugs used in this study can inhibit this effect so that surgical thymectomy has no additional advantage.

I thank Miss Leigh Brown for assistance, and Dr. G. H. Hitchings and his colleagues of Burroughs Wellcome, Inc., for their co-operation in this work and also for providing the purine analogues. I also thank Dr. D. Whitfield, of F.B.A. Pharmaceuticals, Ltd., for providing the actinomycin *C*. This work was financed by grant *G*–62–29 from the Life Insurance Medical Research Fund.

Degraded Carrageenan and Experimental Acute Gastric Ulceration in the Guinea Pig

It has been shown[1] that histamine-induced peptic ulceration in the intact unanæsthetized guinea pig can be prevented or diminished by the oral administration of the sulphated polysaccharide, degraded carrageenan; severe duodenal ulceration could be completely prevented by a dose which at the same time approximately halved the severity of gastric ulceration. It was suggested that degraded carrageenan might augment the natural protection afforded by mucin by complexing with it, so providing a more robust mucosal coating. It has since also been found[2] that in the guinea pig the volume and acidity of histamine gastric secretion is reduced by prior oral administration of degraded carrageenan.

In the experimental results reported here another factor in the protective action of degraded carrageenan on the stomach is described. Acute gastric ulceration caused by histamine has been decreased by the intraduodenal injection of a solution of degraded carrageenan in random bred, male albino guinea pigs of one strain (weight range 300–500 g), where the junction of stomach and duodenum has been sealed by application of a clip or by ligation.

Gastric ulceration was produced in the anæsthetized ('Nembutal' sodium 30 mg/kg intraperitoneally) guinea pig by the subcutaneous administration of histamine acid phosphate (5·0 mg/kg in saline). The peritoneal cavity was opened and an artery clip or ligature placed on the duodenum above the bile duct, to prevent communication between the contents of the duodenum and stomach. 200 mg degraded carrageenan in 1 ml. water were injected into the duodenum in the direction of the pylorus 0·5 h before administration of histamine, and again immediately after the histamine was given; control animals received 1 ml. water instead of degraded carrageenan solution. In a further group of control animals treated similarly but receiving neither histamine nor degraded carrageenan the stomach was apparently healthy at the end of the experiment. The peritoneal cavity was closed by artery forceps and the animal left covered in the supine position on a warm table until 1 h after the injection of histamine, when it was killed by ether. The stomach was removed with the clip in position and the gastric secretion collected. It was filled with water and examined by transmitted light for ulceration. Only clearly established ulcers were considered and these appeared as clean, virtually transparent areas sharply bounded by a whitish opaque margin. This corresponds to the established ulcer carefully described by Watt[3].

Table 1. Anti-gastric Ulcer Effect of Degraded Carrageenan

Treatment	No. of animals	Average severity of gastric ulceration
Control (water)	14	3 +
Degraded carrageenan	14	1·5 +

A 4+ scale was used to grade severity of ulceration: + indicates one or two small areas of ulceration; 2+, one or two larger areas; 3+, several areas of marked ulceration; 4+, extensive ulceration with confluence or impending perforation. Results were averaged for each group and are shown in Table 1.

Thus, 50 per cent reduction in gastric ulceration in 1 h is effected by the sulphated polysaccharide without gaining access to the gastric contents; and this protection compares with that reported[1] in a 24-h experiment where a rather larger (but oily and intramuscular) dose of histamine produced less-severe gastric ulceration, and where a much larger dose of degraded carrageenan was used.

It is suggested that the protection from gastric ulceration given by degraded carrageenan is brought about by events which are initiated in the intestine and probably in the duodenum.

We thank Evans Medical, Ltd., for a gift of degraded carrageenan ('Ebimar').

HÆMATOLOGY

Evidence that 'Normal Incomplete Cold Antibody' is not a Gamma-globulin

Dacie[1] discovered that if normal human red cells were left at 0° C with their own fresh serum and afterwards washed in warm saline, they could be agglutinated by anti-human globulin serum, and he postulated that serum normally contained an incomplete antibody reacting at 0° C with human red cells. Later, Dacie, Crookston and Christenson[2] produced evidence that the positive anti-globulin reactions were not due to the direct detection

of the antibody, but to a reaction with complement which was evidently bound to the cells at 0° C and was not removed by the subsequent washing.

Crawford, Cutbush and Mollison[3] showed that normal incomplete cold antibody had anti-H specificity. Thus the strongest reactions were obtained by incubating group AB serum with group O red cells, and the reactions could be inhibited by the addition to the serum of H-containing saliva.

It has been shown that normal incomplete cold antibody is present in the serum of new-born infants[4,5]. Since it is believed that the only antibodies present in cord serum are those which have been derived from the mother by placental transfer, and since the only γ-globulin transferred is 7*S* γ-globulin (for review, see ref. 6), these observations might suggest that normal incomplete cold antibody is a 7*S* γ-globulin, but this would be surprising since natural antibodies are, at least usually, 19*S* γ-globulin.

The problem was further investigated in the following way: samples of normal adult serum were fractionated by DEAE-cellulose chromatography[7] using a modification described elsewhere[8] and the fractions tested for the presence of normal incomplete cold antibody; in testing fractions, in order to overcome the difficulty of having to supply complement without normal incomplete cold antibody, horse serum was added as a source of complement to the fractions, and the cells were finally tested with immunoconglutinin serum to see if complement had been bound[9]. The normal incomplete cold antibody was recovered in the fractions eluted with 0·10–0·12 M phosphate buffers and was not present in the 0·02 M fraction, in which the bulk of the 7*S* γ-globulin is eluted.

Because normal incomplete cold antibody is thus apparently not a 7*S* γ-globulin, and because it is present in cord serum, the possibility must be considered that normal incomplete cold antibody is not a member of the γ-globulin family at all. Two further pieces of evidence support this view. First, we have found that red cells sensitized with normal incomplete cold antibody are not agglutinated either by potent anti-7*S* γ-globulin or by anti-19*S* γ- (γ_{1M}-) globulin sera. Secondly, we have found that normal incomplete cold antibody is present in approximately normal amounts in the serum of patients with hypogammaglobulinæmia; thus it was present in samples from 10 out of 11 patients, even though some of these samples had been stored at −20° for some years. Table 1 shows three examples; in all three, concentrations of 7*S* γ-, γ_{1M}- and γ_{1A}-globulin were very low, and none of the samples contained iso-agglutinins or the common cold auto-agglutinin anti-I; but all contained normal amounts of normal incomplete cold antibody.

Normal incomplete cold antibody differs in various ways from classical antibodies; thus we have found that it is relatively heat-labile, being destroyed in 30 min at 63° C, that it is absorbed by zymosan (as previously noted by Dr. F. Stratton, personal communication), and that it cross-reacts with certain bacteria. In these ways, normal incomplete cold antibody resembles properdin, and incidentally properdin is present in cord serum[10] and in the serum of patients with hypogammaglobulinæmia[11]. However, we have found that normal incomplete cold antibody and properdin differ in many respects; for example, whereas normal incomplete cold antibody is best absorbed by red cells at 0° C and is absorbed by zymosan just as well at 0° C as at 37° C, properdin is absorbed by zymosan only at 17° C or higher; again, whereas a wide range of bacteria absorb properdin[12], only a few bacteria (for example, *E. coli* C_3) absorb normal incomplete cold antibody.

Quantitation of Erythropoiesis

It was not until recently that a method for the quantitative estimation of erythropoiesis became available[1]. The method introduced requires the application of high doses of radioactive iron, a very stable and sensitive measuring equipment and protracted measurements. The authors showed that the usual calculation of erythrocyte formation from plasma iron-turnover (PIT) values is frustrated by a substantial return of radioiron from the bone marrow into the plasma, starting at about 8 h after injection of radioiron. This finding and the results of Lamerton *et al.*[2] induced me to block the re-utilization of radioiron by injecting inactive iron. Under such conditions PIT would correctly measure iron uptake by the organs of the body, and the radioiron incorporation into erythrocytes would be a correct indicator of the amount of iron built in into erythrocytes. The quotient between the amount of iron contained in the total circulating hæmoglobin and the amount built in into erythrocytes would then be a measure of the effective life-time of the erythrocytes.

Five hæmatologically healthy subjects were examined and their PIT measured[3]. Inactive iron as iron-dextrin ('Ferrigen', kindly supplied by Astra, Södertälje) was slowly injected intravenously, in 100-mg doses, at the indicated intervals. Radioiron incorporation into the erythrocytes was followed for at least 2 weeks to obtain the maximum value. The results obtained are given in Table 1. As even in normal individuals some random destruction of erythrocytes occurs, which according to Mollison[4] is calculated to be about 10 per cent, and as about 1 per cent of the injected radioiron remains in the plasma 8 h after injection, the values calculated were arbitrarily increased with 10 per cent.

It can be seen from Table 1 that the method described leads to values for the erythrocyte life-time which lie within the normal range reported for human beings[4]. The blocking with inactive iron thus proved to be successful in the individuals studied. A complete inhibition of re-utilization cannot be obtained by applying reasonable iron doses; it can, however, be shown that re-utilization

becomes insignificant. Four doses of 100 mg of inactive iron each given at 8 h, 1, 4 and 7 days after injection of radioiron suffice to give the needed blocking effect.

The method described permits the quantitative determination of effective erythropoiesis. From the results obtained the effective erythrocyte life-time can be calculated. In the case of a non-steady-state, appropriate corrections have to be made.

I thank Prof. G. de Hevesy for his advice and Mr. Knut Sletten for his assistance. The financial support given by the Riksföreningen mot cancer and the Jane Coffin Childs Memorial Fund for Medical Research is gratefully acknowledged.

PATHOLOGY

Transplantation of Polyoma Tumours in Rats

IT has been shown that polyoma tumours induced in mice and in hamsters might contain a new cellular antigen[1–4]. The same phenomena were suggested in rats by comparative examination of the transplantability of polyoma and carcinogen-induced and spontaneous tumours in rats[5]. In the work reported here an attempt was made to demonstrate the presence of this antigen in transplantable polyoma tumours in rats and to verify its persistence in tissue cultures derived from primary polyoma tumours. The same antigen was also looked for in rat embryo fibroblasts which underwent a neoplastic transformation *in vitro* by the polyoma virus. No cytopathic effect was observed in this tissue culture, and no virus could be detected after the second *in vitro* passage.

Rats of the inbred strain *R* and Lewis were used. In a first experiment an attempt was made to induce resistance in adult rats to polyoma tumour isografts by pre-treatment (three weekly subcutaneous inoculations) with a homologous transplantable polyoma kidney sarcoma (LKS_1). For challenge, isografts consisting of a transplantable kidney sarcoma (RKS_7), a continuous tissue culture derived from a primary polyoma kidney sarcoma (*38K*) and an *R* rat embryo fibroblast cell line rendered neoplastic *in vitro* by the polyoma virus (*REPT*) were used. No polyoma virus could be recovered from the transplantable tumours or from the continuous tissue cultures. All the isografts were inoculated one week after the last inoculation with homologous tumours and at the minimal cell dose. As control, three other groups of adult rats were treated prior to isografting respectively with a homologous transplantable benzpyrene sarcoma ($LBPS_1$), normal trypsinized and washed Lewis kidney cells and with control medium (Eagle's basal medium with 10 per cent calf serum). The control groups as well as the group treated with a homologous polyoma tumour were also challenged with isologous tumour cells derived from a carcinogen-induced mammary tumour in an *R* rat (*DE7R* cells) and cultured *in vitro*. In a second experiment three groups of adult *R* rats were, prior to isografting, inoculated (three times at weekly intervals) either with a homologous polyoma tumour (LKS_1), with polyoma virus (10^7 $TCID_{50}$) partly purified by one cycle of absorption-elution on cavia erythrocytes, or with control medium. The fourth group consisted of *R* rats inoculated subcutaneously at birth with the virus and isografted with polyoma tumour cells when 2–3 months old. In this group, about half the animals had died of polyoma tumours before the isografts were inoculated. These grafts were a tissue culture derived from a primary subcutaneous fibrosarcoma originally induced by the polyoma virus in an *R* rat (*33F* cells) and the *in vitro* transformed *R* rat embryo fibroblast line (*REPT*).

* Minimal cell dose of isograft to obtain a tumour *in situ* of the inoculation.
† No. of rats bearing tumours 20 days after isografting on total number inoculated. Figures in parentheses indicate number of tumours palpable 12 days after the inoculation.

The results are summarized in Table 1. They indicate (Exp. 1) that pre-treatment of adult rats with a homologous polyoma tumour gives a partial resistance to isografts derived either from a transplantable polyoma tumour, from a continuous tissue culture of polyoma tumour cells or from an *in vitro* transformed rat embryo fibroblast line. They also show that this resistance is only directed against polyoma tumour isografts, is not related to an organ or a connective-tissue specific antigen and is not dependent on the presence of virus in the tumour cells. The results obtained in Exp. 2 show that partial resistance to polyoma isografts is also found in adult rats pre-immunized with polyoma virus and in rats inoculated at birth with the virus. They also indicate that this resistance is highly dependent on the cell dose inoculated as isograft. In the group rats inoculated at birth with the virus and which were still alive at the time of isografting, seven had developed primary polyoma tumours at the end of the experiment. Five of them showed resistance to isografting with 10^6 *33F* cells and one did not. One primary polyoma tumour was detected in the group inoculated with 5×10^7 cells.

The presence of resistance to polyoma tumour isografts in adult rats pre-treated with the virus might be due to the induction by the virus of the same antigen in the cells it infects. These antigenic transformation leads to the rejection of these cells in the adult and immunological competent animal whereas in new-born rats these cells may go further proliferating and eventually give rise to a tumour[3]. There remains, however, to explain why rats injected at birth and tested when adult may show a slight but significant resistance to polyoma tumour isografts. When they do not develop polyoma tumours, one may speculate that the cells infected by the virus, and thereby antigenically transformed, pre-immunized the animal but did not acquire a neoplastic character or were rejected afterwards. When they do develop polyoma tumours and yet are found resistant to the isografts, it becomes difficult to understand why these animals do not reject their own tumours. Although highly speculative, one could, however, consider the hypothesis that rats injected with polyoma virus at birth do not reject neoplastic transformed cells, being immunologically non-reactive, but do not either become tolerant for these cells. At the time their immunological system is built up, in most instances the polyoma tumour cells could be too numerous to be rejected but could pre-immunize the animal sufficiently to enable it to reject a very small inoculum of transplanted isologous polyoma tumour cells.

A Glycosidase Abnormality in Synovial Membrane in Joint Disease

Polysaccharide–protein complexes are known or suspected to undergo depolymerization or incomplete polymerization in rheumatoid arthritis[1], osteoarthritis[2] and intervertebral disk prolapse[3].

We have, therefore, investigated in synovial membrane the activity of enzymes participating in the degradation of oligosaccharides derived from hyaluronic acid[4], and have found an apparent relationship between β-*N*-acetylglucosaminidase activity, and what can be termed clinically the 'reactivity' of various disease processes.

Specimens of synovial membrane were removed at operation from the knee joints of patients suffering from four clinically distinguishable conditions, namely, internal derangements in the acute and in the quiescent state, osteoarthritis, and rheumatoid arthritis.

No true 'normals' can be quoted, as autopsy material was considered not comparable, but it is thought that the group of interval menisectomies—that is, those in whom a torn semi-lunar cartilage was being removed as an elective procedure without any recent trauma—must approximate closely to normal. In order to limit the number of variables involved, all patients were in the age group 25–45 years: senile osteoarthritis is therefore not included, and the group of 'degenerations' comprises those joints in which there was some predisposing cause, such as an old fracture or internal derangement, accompanied by visible fibrillation or actual loss of articular cartilage.

The specimens for assay, identified by serial number only, were placed in dry sterile containers and immediately refrigerated at 4° C. They were then homogenized and assayed for β-*N*-acetylglucosaminidase activity using ρ-nitrophenyl-β-*N*-acetylglucosamine as the substrate[5].

Table 1. β-*N*-Acetylglucosaminidase activity in 35 consecutive specimen. of synovial membrane in four different abnormalities of the knee-joints The results are expressed as micrograms of ρ-nitrophenyl liberated per hour per gram of tissue (wet weight) at 37° C; and are arranged in descending order of activity

No.	Interval menisectomy	Menisectomy with naked-eye hyperæmia of the synovium	Degeneration of meniscus or of articular cartilage	Rheumatoid arthritis

31	2,540			
32	2,160			
33	1,880			
34	1,330			
35				1,060

Thirty-five consecutive specimens gave the results shown in Table 1. No detailed analysis can be undertaken on the basis of this number of estimations, but the general pattern is clear. β-*N*-Acetylglucosaminidase has never been shown to be other than a catabolizing enzyme; and the figures, therefore, confirm that breakdown of tissue is increased in all three abnormalities above, and suggest that the turnover of polysaccharide is much accelerated, both in the so-called degenerative conditions and in rheumatoid arthritis. The wide scatter of results in this last group is puzzling, and may perhaps be associated with cyclical activity of the disease. High enzyme activity tended to be associated with clinical acuteness, as judged on the heat, swelling, and tenderness of the affected joints. There was no apparent correlation with Rose Waaler titre.

The possible relationship of this abnormal enzyme activity to the ætiology of the various processes is interesting, particularly in rheumatoid arthritis, where the enzyme activity is so markedly increased, and where already, on general grounds, there is evidence that enzyme-determined factors are important[6].

The synthesis of 2-acetamido-2-deoxy-gluconolactone, a highly-specific, non-toxic inhibitor of β-*N*-acetylglucosaminidase[5], provides a possible theoretical method of restoring the enzymological balance and perhaps affecting the disease process. However, the clinical results of administration of this enzyme inhibitor to patients with rheumatoid arthritis and allied diseases have so far been unreliable.

We wish to thank Mrs. Patricia Reid for her assistance.

Anoxia and Cerebral Water Content in the Adult Rat

ALTHOUGH there is adequate evidence that anoxia can damage the brain, the precise method by which it does so is not known. It has been suggested that deprivation of oxygen can lead to death of the cell by direct action on the neurone itself[1]. However, an alternative mechanism has been postulated by Lindenberg, namely, that cerebral œdema follows anoxia and this in turn leads to interference with the blood supply of the nerve cells in certain vulnerable areas[2].

Anoxia in man and experimental animals is followed by an increase in water content of the brain[3–5]; but the importance of this in relation to the pathogenesis of brain damage is not understood. This communication describes experiments in which the effects of post-anoxic cerebral œdema and cerebral œdema induced by administration of water were compared, in order to examine some of the possible factors involved in this problem.

The experimental animals were white Wistar rats of either sex, weighing 220–300 g. Unilateral anoxic forebrain lesions were induced in 50 animals by the method of Levine[6], in which the right common carotid artery in the neck was ligated under ether anæsthesia, and the animal exposed to an atmosphere of nitrogen with a sufficient admixture of air to maintain regular respiration but keep the animal comatose. This was maintained for 45 min. More than 70 per cent of the surviving animals were made hemiplegic by this procedure.

At 24 h the brains of the survivors showed swelling of the right forebrain with displacement of the midline structure to the left. There was neuronal degeneration in the cerebral cortex and hippocampus of the right hemisphere, with nerve cell loss especially in the hippocampus. Proliferation of microglia and astroglia was also seen. 60 per cent of the animals did not survive the first 24 h. Some of these died in the nitrogen and death was preceded by fits in about half of them. The rest died 10–20 h after the anoxic episode, and all had convulsions within 2 h before death. No neuronal loss was observed in these rats, but there was shrinking and pycnosis of the cells of the right hippocampus.

A further similar set of experiments was performed, but nine animals were killed immediately after the onset of fits and the brain removed. The water content of the left and right halves of the forebrains was determined by weighing immediately after drying to constant weight at 110° C. The normal water content was similarly determined in the brains of untreated rats. Fits during the anoxic episode were not accompanied by cerebral œdema. However, all rats developing this disturbance 10–20 h after anoxia had a significant increase in cerebral water content ($t = 6{\cdot}5$, $P < 0{\cdot}001$) (Table 1).

Table 1. WATER CONTENT OF FOREBRAINS OF ADULT RATS SUFFERING FROM CONVULSIONS FOLLOWING WATER ADMINISTRATION (150–175 ML/KG INTRAPERITONEALLY) AND ANOXIC–ISCHAEMIC BRAIN INJURY

(Mean values given ± 1 standard deviation, expressed as g water/g wet weight of tissue)

	Control	Convulsions after water administration	Convulsions after anoxic–ischæmia
Water content of forebrain	78·4 ± 0·4	81·0 ± 0·9	Left hemisphere 78·3 ± 1·0 Right hemisphere 81·9 ± 1·3
No. of animals	7	7	9

In the final set of experiments cerebral œdema was produced by the administration of water alone. Convulsions were induced in adult rats by the intraperitoneal injection of 150–175 ml./kg of distilled water, 10 min after intramuscular injection of 1 U. of vasopressin B.P. The average water content of the brain at the commencement of fits was found to be 81·0 ± 0·9 per cent (seven animals). At this stage further injections of water were found to be fatal. 24 h after this, six animals were killed and the brain examined histologically. No loss or degeneration of nerve cells, or glial reaction, was seen.

These findings indicate that, in the rat, cerebral œdema follows both anoxic–ischæmic encephalopathy and overhydration. The results suggest that convulsions and subsequent death in the early post-anoxic period could be due to an increase in the cerebral water content alone, because in both the anoxic and overhydrated groups the degree of œdema was similar when convulsions began. Previous work in this laboratory supports this interpretation[5], as it was shown that there was significantly fewer deaths from severe anoxic–ischæmic encephalopathy following administration of 30 per cent urea, which decreased the degree of cerebral œdema in all affected animals.

Cerebral œdema was not found in animals dying during the initial anoxic episode, in whom other metabolic or physiological factors must cause death. As degeneration and loss of nerve cells did not follow cerebral œdema produced by water administration, it may be concluded that brain swelling alone cannot lead to the destruction of neurons. This does not necessarily disprove Lindenberg's hypothesis, because anoxic brain injury could be the consequence of several factors acting together, and in the presence of circulatory and metabolic disturbances, œdema could potentiate their effect.

This work was supported by the Spastics Society.

HISTOCHEMISTRY

Changes of Coenzyme (TPN) Diaphorase and TPN-linked Dehydrogenase during Axonal Reaction of the Nerve Cell

EXAMINATION of the axonal reaction of the nerve cell has revealed a high level of metabolic processes. Lipid, protein and RNA content[1,2], increase and changes in the activity of various enzymes have been described[1,3,5,6,8]. Most of the histochemical investigations of the enzymes in this field were carried out on anterior horn cells or on dorsal root ganglia after cutting the sciatic nerve. A disadvantage of this is the normal variability of enzymatic activity, especially in the spinal ganglia. Difficulty is also encountered in cryostat material in differentiating a normal cell from a chromatolytic cell.

In order to avoid these difficulties, investigations were carried out on the nucleus facialis after unilateral transection of the nerve.

30 adult guinea pigs were used. The n. facialis was cut at its exit from the skull at the foramen stylomastoideum. Animals were killed after 1, 3, 5, 6, 7, 8, 9, 10 days and after 2, 3, 4, 5, 6, 7, 8, 10, 14 weeks.

20-μ thick cryostat (model Dittes–Duspiva) sections were incubated with the appropriate substrate and the tetrazolium salt nitro-BT or tetra-nitro-BT according to the technique of Nachlas *et al.*

The following enzymes were investigated: TPN-diaphorase (TPN-D), the dehydrogenase of 6-phosphogluconate (6-PG) and glucose-6-phosphate (G-6-P). Activity of TPN-D, which is very weak in normal cells of the nucleus facialis, increased significantly from 5–50 days. During this interval, G-6-P-dehydrogenase shows a marked increase of enzymatic activity while that of 6-PG-dehydrogenase increased slightly. Changes in the activity of TPN-D and G-6-P-dehydrogenase were relatively stronger and more persistent than DPN-diaphorase and DPN-linked dehydrogenases.

The results recorded here suggest a relation between the increase of enzymatic activity and the well-known changes in lipid and ribonucleotide content[2,7]. The increased activity of G-6-P-dehydrogenase and 5-PG-dehydrogenase was interpreted as an indication of an increased activity of the pentose phosphate pathway. Thus it may be possible to yield more pentose for an increased RNA-synthesis. On the other hand, the 'Horecker'-cycle is also a source of TPN-H, which is of importance for fatty acid synthesis by delivering 'reductive equivalents'. This may be the basis for increase of lipids in the chromatolytic nerve cell.

The histochemically demonstrated increase of enzymatic activity well supplements microchemical findings. There is no support for an enzymatic depletion of regenerating neurones as postulated by Friede[4]. Only some degenerative neurones show a decrease of oxidative enzymes.

HISTOLOGY

Minute Structure of the Inner Surface of an Embryonic Central Nervous System

F. Sauer[1], referring to mitosis in the neural tube, wrote: "The attachment of the neural tube cells to each other at the surface bordering the lumen appears to play an important part in the mechanics of the development of the neural tube". Having been preceded in general conception by other authors[2–4], he stated that elements of neural epithelium were attached to each other at the surface bordering the lumen by a terminal bar net, and that there was "no internal limiting membrane other than the cytoplasmic membrane of cells". In spite of this statement, the old conception of His[5] describing the internal limiting membrane as a felt-work of fibrils into which passed the cytoplasmic fibrils of the spongioblasts had been generally accepted. Later on, Sauer's suggestion was revived by further authors[6–11]; but none of them elaborated the minute structure of internal limiting membrane or considered its possible significance in ontogenesis.

We tackled this problem during an investigation of the phenomenon of 'overgrowth' of the neural tube and had occasion to examine the structure of internal limiting membrane by means of electron microscope, thin membranous preparations and replica method. Our work with histological preparations, verified by mathematical calculations, has shown the internal limiting membrane to consist of two types of polygonal fields arranged into two layers, representing terminal enlargements of cytoplasmic end-feet of all germinal zone cells (Fig. 1). The fields of the superficial layer are designated as 'principal', that of the deeper layer as 'subsidiary' fields. The 'principal' fields are attached to each other by distinct cementing borders of the first order, the 'subsidiary' ones by finer cementing borders of the second order. Amid every field is situated a low cytoplasmic hillock with a subjacent centriole. The whole system, in geometrical abstraction, is shown in Fig. 2. The mean field area does not remain constant but progressively diminishes in the course of development as a result of our measurements carried out on the mesencephalic region of chicken embryos, and illustrated in Fig. 2. The rate of the decrease is maximal during the period of neurulation. From the third day of incubation, the absolute mean size of fields practically does not change at all. From these observations several suggestions may be put forward:

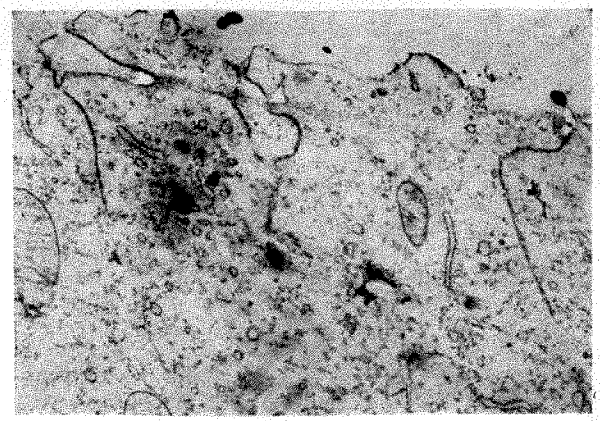

Fig. 1

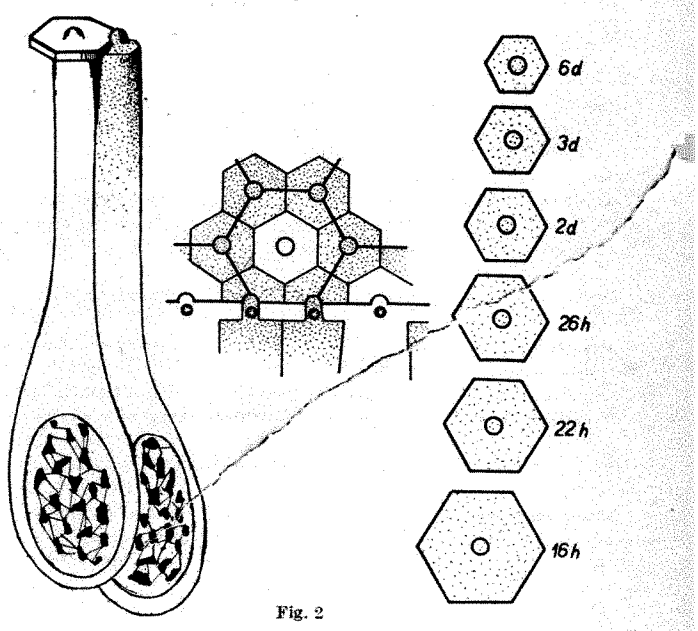

Fig. 2

(1) The internal limiting membrane system determines polarity of the neural tube proliferation structure, anchoring the cytoplasmic 'feet' of all intermitotic cells.

(2) The mean field area rapidly diminishes during neurulation, indicating the ensuing disproportion between areal extension of the neural plate and volume of cells anchored in its internal limiting membrane system. It is suggested that this process is essential for closure of the neural tube.

(3) The number of cells bound in the internal limiting membrane system is limited by the surface extension of ventricular cavities and the mean field area. With the constant field area, lateral migration of released neuroblasts, constituting the mantle zone, and surface growth of cerebrospinal fluid spaces are interdependent phenomena.

(4) At the end of proliferation phase, the 'principal' elements differentiate into ependymal cells, while the 'subsidiary' ones change either into sub-ependymal layer or migrate towards the periphery.

Experimental evidence has been obtained that regeneration of the internal limiting membrane system was limited to initial stages of neural development only. On the following stages it may be easily disintegrated by a wide range of noxious factors, resulting in distortion of proliferation structure with serious effects on later morpho-

genesis of the central nervous system[12–14]. Destruction of the internal limiting membrane system often causes and regularly accompanies the development of malformations of the central nervous system.

The possible relation between relative field area and proliferation intensity, and origin of the internal limiting membrane system in the process of induction are the matter of further investigation.

Another Variable to be observed in Autoradiographs

Autoradiography is a technique which reveals the sites of radioactivity in an object by means of a photographic emulsion. The object is brought into close contact with the emulsion and after a suitable period of time the emulsion is processed by photographic development. In such a preparation the sites of radioactivity are indicated by the presence of silver grains in the emulsion. At present, regions of an autoradiograph are regarded as different if the densities of their silver grains, in terms of some attribute of the object, are different. It may be possible to use another property of the grains to show that regions are different. This property is the way the grains are distributed in clusters.

The silver grains in autoradiographs of biological tissues prepared for light microscopy are not all present as single grains; some are present in clusters. The clusters can be arranged in sizes according to the number of grains they contain. It is possible to decide how many grains are in a cluster by examination of its outline. The number of clusters of each size can be counted over one area if a suitable micrometer is in the ocular of the microscope. When all the grains have been counted in one area a table of the frequency with which they are present in each size of cluster can be prepared.

Consider the hypothetical situation in which an isotope is present in a layer on a microscope slide and the isotope is distributed at perfectly regular intervals in the layer. It is possible for all the tracks of emission from the isotope to be only just separate. If this were so the frequency with which grains in the autoradiograph occurred in the various size of cluster would be determined by: (1) the thickness of the layer containing the isotope; (2) the ability of the layer to filter the emission; (3) the energy spectrum of the emission; (4) the thickness of the photographic emulsion; (5) the way in which the halide crystals are packed in the emulsion; (6) the number of halide crystals per unit area of emulsion; (7) the size of the halide crystals; (8) the number of developed grains per unit area.

Now consider the hypothetical situation in which the isotope is concentrated in small particles which are distributed at regular intervals in the layer. If the number of grains per unit area is the same as before, then the tracks of the emission must overlap. The frequency of single grains is decreased and that of clusters increased in comparison to their frequencies when the distribution of the isotope is perfectly even. The extent of the effect would be determined by the amount of the isotope in each particle and the size of the particles.

In practice the variations inherent in the technique are controlled best when observations on clusters are made under the following conditions: (1) regions of the same tissue section are compared which have the same number of grains per unit area; (2) the emulsion is affected by a single emission; (3) when more than one section is used, they should be on one microscope slide, covered by a single continuous layer of emulsion, and processed together.

If these precautions are taken, any difference in the frequency with which grains occur in the various sizes of cluster will reflect a difference in the distribution of the isotope in the section. With short-range emissions, like that of tritium, the greatest change can be expected in the frequencies with which grains are present as single grains and triple grain clusters.

Observations on this variable have been made in an experiment on the incorporation of tyrosine into the growing hair of rats. The tyrosine was generally labelled with tritium. Autoradiographs prepared from 2 rats killed 30 min after injection of the labelled tyrosine show three regions of the hair cortex over which the number of grains per unit area is the same. The three regions are the matrix of the hair bulb, the cortex of the upper bulb at the level of the top of the hair papilla, and the cortex just below the level of its complete keratinization. As a different process is performed in the cells at each of these sites it is reasonable to expect that the incorporation of tyrosine might be carried out in different manners. A table of the frequencies with which the grains are present in the sizes of cluster up to triple grains was prepared for each of the three levels. This was done for three hairs in each animal. The results from all the hairs are similar to those shown in Table 1. The percentage of single grains is lower for the shaft than for the matrix and upper bulb. The percentage of grains in clusters of three is higher for the shaft than for the matrix and upper bulb. The percentage of grains in clusters of two is similar for all three levels. No difference is apparent between the frequencies of the matrix and the upper bulb.

Table 1

	Matrix	Upper bulb	Shaft
Percentage of single grains	40	45	24
Percentage of grains in cluster of 2	22	35	25
Percentage of grains in cluster of 3	17	8	37

The percentage of the total number of grains present in the size of cluster indicated in three regions of one growing hair.

The constant difference between the shaft and the other regions in the six hairs is shown to be significant at the 5 per cent level ($P = 0{\cdot}016$) by the sign test. It is concluded that the labelled tyrosine incorporated into the hair cortex is distributed more evenly in the matrix and upper bulb than in the shaft just below the level of full keratinization. The difference could be produced by the presence of the isotope in different cell components, or the presence of the isotope in the same components under different spatial conditions. A full report and discussion of this experiment on protein synthesis will be published elsewhere.

The experiment illustrates the use of the method to show that regions of a tissue have incorporated a tracer in a different way at the same time interval after its administration. On suitable material it may be possible to demonstrate changes in the same region at different time intervals by this method.

I thank Prof. Leblond for his advice on the experiment with radioactive tyrosine which was performed at McGill University during the tenure of a Wellcome research travel grant. The work was supported by a grant from the Medical Research Council of Canada.

BIOLOGY

A Strain of *Peronospora tabacina* Pathogenic to Tobacco Lines with Resistance derived from *Nicotiana debneyi* and *N. goodspeedii*

The occurrence of strains of *Peronospora tabacina* Adam. (blue mould of tobacco) as suggested by Hill[1] has now been confirmed.

Conidia of *P. tabacina*, from susceptible varieties growing at Canberra, A.C.T., and at Myrtleford, Victoria, were used as inoculum for separate lots of plants of the susceptible variety Virginia Gold and the resistant variety SO_1 (ref. 2). After 4 or more days, depending on temperature, symptoms of the disease were obvious on leaves of the susceptible variety and extensive sporulation occurred on the following morning. Small chlorotic flecks that failed to sporulate appeared on young leaves of the resistant variety. Three or more days later, one to three sporulating lesions appeared on some of the resistant plants that had been inoculated with conidia from either source.

Conidia produced on SO_1 plants following inoculation with the pathogen from Canberra were used to inoculate alternate leaves of three SO_1 plants from which the flowers, and all except 4–5 leaves, were removed. The remaining leaves, inoculated with conidia from a susceptible variety, served as controls. Results at 8 days after inoculation are shown in Table 1. An SO_1 plant destroyed by blue mould is shown in Fig. 1.

Table 1

Plant *A*		Plant *B*		Plant *C*	
Leaf size (cm)	No. of sporing lesions	Leaf size (cm)	No. of sporing lesions	Leaf size (cm)	No. of sporing lesions
30 × 18	24	26 × 16	18	27 × 16*	0
31 × 18*	0	29 × 18*	0	34 × 20	42
35 × 18	12	32 × 19	19	41 × 20*	1
34 × 17*	0	36 × 19*	0	41 × 19	28
		38 × 18	56	43 × 21*	0

* Leaves inoculated with conidia from Virginia Gold plants. Other leaves inoculated with conidia from SO_1 plants.

In the susceptible variety, the disease appeared earlier, and its progress was more rapid, when the plants were inoculated with conidia from susceptible varieties than when inoculated with conidia from SO_1 plants. Rates of development were similar in SO_1 seedlings inoculated with conidia produced on SO_1 plants and in Virginia Gold seedlings inoculated with conidia produced on Virginia Gold plants.

Seedlings of the resistant lines *Bel*-61-12 (ref. 3) from the United States, Fixed *A*2 hybrid[4] and two lines[2] with resistance derived from *N. goodspeedii* Wheeler were all susceptible when inoculated with conidia produced on SO_1 plants.

Resistance in the SO_1 variety is derived from *Nicotiana debneyi* Domin. In another test, a line with resistance derived from *N. goodspeedii* was inoculated with conidia from a susceptible variety, and sporulating lesions indistinguishable from those reported for SO_1 were produced.

The results show that the *P. tabacina* used in these experiments is a mixture of a major and at least one minor component. When propagated on the normal susceptible commercial varieties, the major component appears to have a selective advantage over the minor component. However, propagation on genotypes resistant to the major component excludes the operation of this selective advantage and the minor component builds up rapidly.

As *P. tabacina* in Europe is considered to be of Australian origin, results obtained in Australia may be applicable in Europe. In Australia, resistant lines of tobacco have not been released for commercial production, consequently the situation in the fields will remain unchanged. However, it would appear that extensive use of resistant varieties now becoming available could be followed by a build-up of the strain to which they are susceptible.

Nitrogen Fixation by the Leaf-nodule Endophyte of *Psychotria bacteriophila*

Investigations of the symbioses in root-nodules of legumes and non-legumes have established that nitrogen fixation occurs in the nodular tissue[1]. Although some reports have appeared describing the leaf-nodule symbiosis in *Psychotria*[2–4] no isolate of the endophyte is at present available, and it has not been unequivocally established that nitrogen fixation is involved. We now report that the isolated endophyte fixes atmospheric nitrogen in pure culture and, apparently, in the plant as well. It is known that plants either naturally or experimentally freed of the endophyte are dwarfs[2,3]. Nitrogen fixation does not fully account for these observed effects.

The endophyte has been repeatedly isolated in pure culture from germinating seedlings on either nitrogen-free mineral agar or trypticase soya agar. Although the isolates obtained from both media were identical the N-free medium is preferable for isolation purposes, since contaminating non-fixing micro-organisms are thereby eliminated. The isolate, which we have identified as a species of *Klebsiella* by serum agglutination tests, was a Gram-negative, motile, non-acid fast, non-spore forming rod with terminal refractile granules.

Growth in nitrogen-free glucose broth was delayed for 4 or 5 days until the evolution of gas was observed. When an 80 per cent nitrogen–20 per cent helium mixture was used as the gas phase there was little delay in growth and both the growth rate and the total crop were greater than that obtained with cells grown in air.

Nitrogen fixation was demonstrated directly using a nitrogen-15 enriched gas phase. Cells were grown on nitrogen-free mineral agar for 4 days, aseptically suspended in sterile 0·1 M, *p*H 7 phosphate buffer and inoculated into 4–5 l. of the nitrogen-free culture solution in an 11-l. carboy. High-purity nitrogen was sparged through the culture for 48 h. The cells were collected aseptically by centrifugation and 10 ml. of a thick suspension of cells (≈3 mg nitrogen) in a mineral salts solution were treated with various gas mixtures as indicated in Table 1. Leaf homogenates were made by cutting small pieces of surface sterilized leaves with a razor blade followed by grinding in an all-glass TenBroeck homogenizer in 0·1 M. *p*H 7 phosphate buffer. After exposure to the labelled gas, the cells were digested by conventional Kjeldahl method using a mercury catalyst. The digests were distilled into hydrochloric acid and converted to nitrogen

Table 1. NITROGEN FIXATION BY AN ENDOPHYTE OF *Psychotria*

Exp. No.*	Tissue	Gas phase (atm.)	Hour shake 28° C	Atom % Excess ^{15}N †
1	Homogenized nodulated leaves			0·029
	Homogenized nodulated leaves, boiled	0·7 $^{15}N_2$ 0·1 O_2 0·2 He	16	0·000
	Isolated endotype, not adapted			0·039
2	Isolated endophyte, adapted	0·8 $^{15}N_2$ 0·2 He	24	0·049
3	Isolated endophyte, adapted + Na pyruvate	0·5 $^{15}N_2$ 0·5 vac.	24	0·849

* In experiment 1 the $^{15}N_2$ was 95 atom per cent excess ^{15}N; in experiments 2 and 3, 30 atom per cent excess ^{15}N.

gas by alkaline hypobromite oxidation according to the method of Sims and Cocking[5]. Isotope ratios were determined with a Consolidated Electrodynamics model 21–130 mass spectrometer.

The results in Table 1 show that cells grown in tryptic case soya broth had a slight enrichment of nitrogen-15 which was increased by growing the cells without combined nitrogen. The addition of 10^{-3} M sodium pyruvate greatly increased the isotope incorporation in the cells. There was a small but significant fixation of nitrogen in homogenates of nodulated leaves, but this was not readily reproduced. In this experiment, oxygen was in the gas phase since it has not yet been established that fixation in the isolated endophyte occurs under anaerobic conditions. Since nodulated plants have been maintained in vermiculite supplied with nitrogen-free nutrient solution for more than 6 months without any signs of nitrogen deficiency, it is clear that nitrogen fixation undoubtedly occurs in these plants.

Although nitrogen fixation is a factor in this association, it does not explain the striking effect of the endophyte on the growth of the plants because non-nodulated dwarf plants do not recover even when supplied with various forms of combined nitrogen or when potted in soil. Since the dwarfing effects are modified but not completely reversed by the application of gibberellic acid, it is likely that the main effect of the association involved the production of plant growth substance(s) as yet unidentified.

So far as we are aware, this is the first demonstration of a micro-organism in association with a higher plant in which the endophyte fixes atmospheric nitrogen in pure culture and presumably also in the plant. A more detailed account of these studies will appear elsewhere.

This work was supported by the U.S. National Institutes of Health (*GM*-08577) and the U.S. National Science Foundation (*G* 2140).

Note added in proof. Cell-free extracts of the *Klebsiella* convert pyruvate to hydrogen, carbon dioxide and acetyl phosphate. Electron paramagnetic resonance spectra of these extracts show strong signals for manganese (gauss 2·01) and for non-hæm iron (gauss 1·94) and are similar to the spectra observed for extracts of *Clostridium pasteurianum* that fix nitrogen gas (Nicholas, D. J. D., Wilson, P. W., Heinen, H., Palmer, G., and Beinert, H., *Nature*, **196**, 433; 1962).

Tissue Cultures of Juvenile and Adult Specimens of Ivy

Robbins[1] and Wareing[2] have suggested that chemical or cellular differences are the basis of the striking dimorphism of the juvenile and adult growth phases of some plants. The following experiments support this view and show that differences can persist through repeated sub-cultures of tissues *in vitro*.

The English ivy, *Hedera helix* Linn., exhibits marked dimorphism in the different growth-phases. The juvenile forms are vines with flattened stems, with dorsiventral leaf arrangement, with palmately lobed leaves and aerial roots. Red pigments are also common in stems and petioles. On the other hand, the mature or adult form produces a shrubby, upright growth with entire leaves and the stems rarely produce roots.

The following experiments present comparisons of tissue cultures grown both from adult specimens and from juvenile reversion shoots on the same plants. These were occasionally observed to occur spontaneously at the bases of adult plants by Stoutemyer and Britt[3].

Stems approximately 0·5 cm in diameter were washed and the epidermis stripped off. Pieces of tissue approximately 2 mm² and weighing 1–2 mg were removed with a sterile scalpel and the cambial side laid on agar slants. Cultures were sometimes started from cross-sections of thin stems. The cultures were grown in diffused light or in darkness at temperatures of from 20° to 32° C. A temperature of 27° C permitted excellent growth of all types of tissue. At 24° C or lower, sub-cultures were difficult to maintain except when taken from young seedlings. Sub-cultures likewise deteriorated at 32° C.

Extensive trials of numerous culture media led to successful sub-cultures of *H. helix*. The two best media have been White's[4] medium or a modification based on a suggestion of Shantz and Steward[5] in which potassium nitrate was reduced to 47·0 mg per litre and 60 mg of ammonium chloride was added. The latter was used in the following experiments. With both formulations, the following supplements were added to each litre: (*A*) fresh coconut milk was filtered through a No. 1 Whatman paper, autoclaved at 15 lb. for 30 min and stored in the refrigerator. It was re-filtered and 100 ml. was added before the prepared medium was autoclaved; (*B*) enzymatic casein hydrolysate powder, 200 mg, and inositol, 100 mg. Requirement of the latter has not been established; (*C*) naphthalene acetic acid, 1·0 mg.

6 g Difco 'Bacto Agar' were added to each litre of the nutrient, which was prepared with glass-distilled water. The medium was adjusted to *p*H 5·8 with 0·1 N sodium hydroxide before autoclaving. 4- or 6-dram flint glass vials with plastic caps were most convenient for the sub-cultures.

The appearance of typical adult and juvenile tissue cultures of *Hedera helix* after 24 weeks from the initial inoculation is shown in Fig. 1. Sub-cultures were stable and consistent in performance if transfers were made at monthly intervals, and were used for quantitative comparisons of growth-rates. The behaviour of sub-cultures of juvenile and mature stems from the same

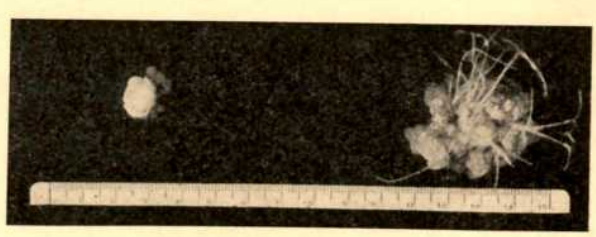

Fig. 1. Growth of tissue culture from adult and juvenile stems from same plant of *Hedera helix* showing appearance after 24 weeks. Left, mature tissue, weight 0·588 g; right, juvenile tissue, weight 6·780 g with abundant root formation

Table 1. Growth of Tissue Cultures from English Ivy Stems expressed as Ratios of Final to Initial Weights. All Means are based on 100 Cultures, Except where Stated

Order of transfer	Source of tissue	Temperature 24° C	Temperature 27° C
First sub-culture	Young seedling	(30) 11·75	(10) 16·19
	Juvenile reversion	4·01 ± 0·31	8·20 ± 0·72
	Adult	1·44 ± 0·17	4·06 ± 0·50
Second sub-culture	Young seedling	—	10·96 ± 0·60
	Juvenile reversion	—	7·69 ± 0·46
	Adult	—	5·50 ± 0·36

plant is shown in Table 1, together with a similar culture taken from a young open pollinated seedling derived from the same plant. The weighings of the tissues were made on a small torsion balance using sterile techniques. Standard errors were calculated from 10 values each representing the mean of 10 cultures.

The higher temperature was preferable, particularly with cultures of mature tissues. The exceptionally high growth-rate of the cultures from the very young seedling should also be noted.

These results explain those reported by Privat[6], who, using a similar culture medium, was not able to establish sub-cultures from ordinary juvenile or mature stems of ivy, although the original cultures grew well. However, when very young seedlings were used, tissues from these stems could be sub-cultured successfully. Apparently the range of temperatures (22°–25° C) was too low to permit success with any but the latter type of tissue.

Sub-cultures from juvenile reversion and adult stems of *Hedera helix* transferred through nine generations at monthly intervals continued to show differential rates of growth. Typical responses are shown in Table 2.

Table 2. Growth of Tissue Sub-cultures from English Ivy Stems expressed as Ratios of Final to Initial Weights (Means of 50 Cultures at 27° C)

Order of transfer	Juvenile reversion	Adult
Seventh sub-culture	5·6 ± 0·4	4·4 ± 0·3
Eighth sub-culture	4·8 ± 0·4	3·9 ± 0·5
Ninth sub-culture	6·8 ± 0·5	5·7 ± 0·4

Experience with more than 13,000 sub-cultures during the past year has shown that those from juvenile stems maintained more than 20 per cent higher growth-rates than those from adult type tissue. Another marked difference was the considerably greater amount of root formation in the cultures taken from juvenile stems.

Systemic or Semi-systemic Infection of Wheat with *Puccinia graminis tritici*

Eriksson[1] proposed the mycoplasm theory according to which rusts could persist in wheat seeds and thus produce systemic infection of wheat. Hungerford[3] and Mehta[4], however, could not substantiate the theory of mycoplasm.

Apparent systemic or semi-systemic infection in wheat seedlings with *Puccinia graminis tritici* was produced in test-tubes using the technique of inoculation described by me[2]. The variety of wheat used in these investigations was a club type from Afghanistan, locally known as 'Lucchak', and the stem rust race used for this work was a biotype of race 21 isolated from the country. This biotype differed from the key race 21 in that it produced a 1+ type of infection on Vernal, whereas the key race produces an O type of infection on that differential variety.

In an experiment with fifty seedlings, uredospore suspension of the stem rust fungus was injected with a hypodermic needle No. 18 near the growing point of 60–72-h. old wheat seedlings on May 22, 1962. All the seedlings showed infection with stem rust on the first leaf on May 29–31, 1962. However, in two of the seedlings in which rust pustules appeared on May 29, stem rust appeared on the second leaf on June 6, 1962, on the third leaf on June 11, and on the first tiller on June 14. Similar infections were also obtained in 3–4 per cent of the inoculated seedlings in test-tube experiments carried out in June 1962. This, therefore, shows that in those seedlings the infection with stem rust was of a systemic or semi-systemic type.

In another experiment seedlings were raised from surface disinfected seeds, and the inoculated plants when they showed infection on the first and second leaves were pulled out of the agar in the tube. The leaves and the rudimentary leaves enclosing the growing point were removed right from the base of the growing point so far as possible and the growing point tissue crushed on a slide. The undifferentiated tissue material on staining with cotton blue revealed the presence of hyphæ and uredospores of the rust fungus. It would, therefore, be seen that if stem rust of wheat could be established in the growing point of wheat seedlings, subsequent unfolding leaves would show infection with rust fungus.

Systemic infection of a mature wheat plant with stem rust was observed by me under field conditions in wheat variety Purdue 5759*B*4–5–3 listed as entry No. 93 of the International winter wheat rust nursery of 1962, seeds of which were received from Dr. W. Q. Loegering, of the U.S. Department of Agriculture. One wheat plant of this variety with 7 tillers showed 40 per cent rust infection on all the leaves and heads on May 15, 1962, when other varieties and the local varieties did not show a trace of stem rust infection. Stem rust must have appeared on this variety at least 10 days earlier. Stem rust infection was first noted in traces on the local variety and some other varieties on May 29, 1962.

Effect of Raw Wheat Germ on Nutrition of the Chicken

During our investigations on the nutritional aspects of human sprue designed to find an experimental animal which might help in our basic understanding of this disease, we noted reports by Creek[1] that wheat germ had a deleterious effect on growth of chickens and that this was associated with an apparent increase in fat content of fæcal droppings. After further examination of his experiments[2] and after seeing the degree of 'contamination' of the raw wheat germ with flour as it comes from the mills, we felt that his results could possibly be accounted for by the adverse effect of gluten in the adherent flour.

Early experiments confirmed Creek's findings of poor growth and the fæcal fat[3] was as high as 20 per cent of fat intake in the wheat germ groups. When gluten was given as a substitute for the corn in the diet, however, we found that the birds fed gluten grew slightly better than controls ($P < 0{\cdot}0125$) and there was no difference in fæcal fat content.

Table 1

	Day 1		Day 28		Day 7–14
	No. of birds	Mean wt. (g and S.E.)	No. of birds*	Mean wt. (g and S.E.)	Fæcal fat as % fat intake
Basic diet + raw wheat germ (1)	36	38·3 ± 0·47	33	461·0 ± 9·8	24·6
Basic diet + raw wheat germ (2)	36	38·3 ± 0·52	34	487·6 ± 12·6	20·3
Basic diet + corn (controls)	36	38·3 ± 0·48	33	567·0 ± 12·5	7·9

* 8 birds died.

In further experiments (Table 1) carried out with the co-operation of the Poultry Division of Michigan State University, we re-confirmed these findings. Three replicates of 12 Arbor Acre males were used for each diet. The controls were fed a basal corn diet, the test groups had a similar diet, but raw wheat germ (40 per cent) was substituted for corn. The raw wheat germ was from two different sources. In similar experiments we were able to show that by autoclaving the raw wheat germ before adding it to the diet the effects were no longer evident (Table 2). All diets contained 15 per cent fat.

Table 2

	Day 1		Day 21		Day 7–14
	No. of birds	Mean wt. (g and S.E.)	No. of birds*	Mean wt. (g and S.E.)	Fæcal fat as % fat intake
Basic diet + autoclaved wheat germ	36	34·9 ± 0·26	28	220·8 ± 6·8	9·72
Basic diet + raw wheat germ	36	35·5 ± 0·26	31	165·8 ± 5·4	21·10
Basic diet + corn (controls)	36	35·4 ± 0·23	33	199·8 ± 3·7	9·73

* 16 birds died.

Creek believes that these results might be caused by a thermolabile toxin in the raw wheat germ which is destroyed on heating[4].

From close observations during all our experiments where raw wheat germ was part of the diet it became obvious that during and after feeding the food formed a paste on the beaks in combination with salivary mucus and water and that these birds ate correspondingly less and hence grew less well. We also repeatedly noted the way the birds cleaned their beaks on the wires of the flooring, thus adding sufficient food fat to the droppings to account for the difference in fæcal fat figures between control and wheat germ groups.

In one experiment where the wheat germ formed 55 per cent of the diet, the stickiness was so apparent and the depression of growth so great ($t = 12{\cdot}8$, $P < 0{\cdot}0005$) that the birds died of starvation. Autoclaving the raw wheat germ alters its consistency markedly so that it becomes drier and does not form a sticky paste; the birds eating it without difficulty.

In these experiments there were no macroscopic, microscopic or electron microscopic changes in the bowel mucosa such as those seen in human cœliac-sprue. We have thus been able to confirm Creek's original work, but think our observations offer a simple and reasonable alternative explanation for the effects of raw wheat germ and we believe can save a fruitless search for a non-existent toxin.

Use of Ear Chamber with Uterine Muscle Transplant to differentiate Myometrial and Vascular Activity

The Sandison[1,2]–Clark[3] rabbit ear chamber technique has been used extensively for the study of mammalian tissues *in vivo*. The type of ear chamber used in the present investigation[4] was constructed mainly of 'Perspex' as in the Sandison–Clark chamber but has been adapted for removal of coverslip for implantation of grafts after the method of Williams and Roberts[5]. It has been shown that within such grafts the vasculature of the donor organ persists[6].

It occurred to us (J. D. M. and W. J. C.) that prolonged investigations of uterine action could be made by this method, for in the past it has been difficult by conventional methods to study vascular activity in relation to myometrial activity in the uterus. The possibility that in some instances the uterine contractility might be secondary to vasoconstriction has been suggested because of the delayed occurrence of contractions produced by ergotamine as compared with oxytocin or ergometrine[7].

An ear chamber was therefore inserted in a non-pregnant female rabbit's ear under sterile conditions. The chamber was observed frequently following its insertion, and it was noted that new vessels gradually filled the observation space. After complete healing, minute grafts of uterine muscle were placed in the chamber. Following re-establishment of circulation in the grafts the animal was mated, and progressive hypertrophy of the graft was observed

A *B*

Fig. 1. Photoelectric record showing vasoconstriction (*A*) and myometrial contraction (*B*) of uterine muscle graft

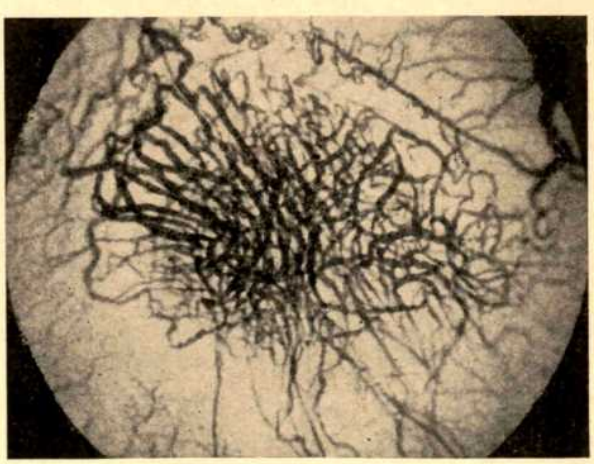

Fig. 2. Uterine muscle graft (normal appearance, × *c.* 18)

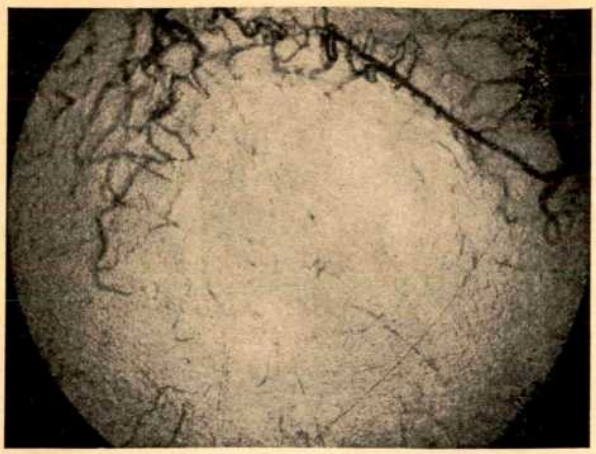

Fig. 3. Uterine muscle graft (vasoconstriction, × *c.* 18)

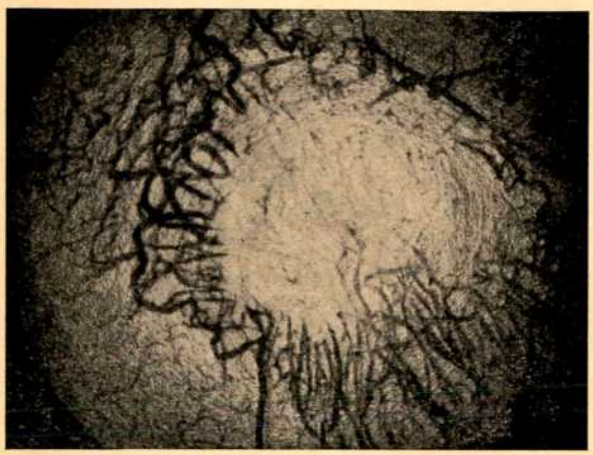

Fig. 4. Uterine muscle graft (myometrial contraction, × *c.* 18)

during pregnancy and involution was seen to occur *post-partum*.

On the administration of drugs or stimuli these grafts showed two types of response—vasomotor and myometrial contractions. Either led to blanching of the field. However, myometrial contractions produced a movement of the muscle into a spherical shape and a reduction in size of the entire graft. Photographic records were made of the preparation and observations were made on the unanæsthetized animal.

A simplified method of observation suggested by Dr. C. N. Smyth was to record the changes in transmission of light through the chamber as the vessels dilated or constricted. Using infra-red reflecting and green filters and a cadmium sulphide photo-resistive cell placed above the microscope optical cross-over outside the eyepiece, two types of tracing were obtained which could be correlated with simultaneous optical observation of the responses. A binocular microscope with the recorder attached to one eyepiece made simultaneous observation possible.

In 'pure' vasoconstriction the rate of light transmission change was slower than in 'pure' myometrial response (see Figs. 1*A* and 1*B*, which correspond to the changes between Figs. 2 and 3 and 2 and 4, respectively). As a preliminary investigation the effect on the graft of loud noises, oxytocin, ergometrine, ergotamine, serotonin, adrenaline and noradrenaline have been examined before, during, and after pregnancy.

The tentative conclusions of this first investigation were that this was a useful method of observing the mode of action of oxytocic drugs. The uterine graft became progressively more sensitive to oxytocin as pregnancy advanced and its vasoconstrictor responses could be abolished by chlorpromazine, enabling study of the muscle action alone.

The work is being continued by one of us (C. A. M.) with the help of a grant-in-aid from the Fotheringham Research Fund of the Australian Regional Council of the Royal College of Obstetricians and Gynæcologists and by another (W. J. C.), who is a Research Fellow of the National Heart Foundation of Australia. We thank Mr. R. Fleay for making the electronic recording apparatus.

Temperature and the Rate of Ageing in Poikilotherms

Two theories, which I shall call the 'rate of living' and the 'threshold' theories, have been suggested to explain the fact that poikilothermous animals live longer at low than at high temperatures. In this communication these theories are explained, and an experiment described which decisively contradicts the rate of living theory.

The rate of living theory (Fig. 1*A*), put forward by Pearl[1], suggests that the greater longevity at low temperatures arises because the rates of ageing processes, like those of chemical reactions, are greater at higher temperatures. This theory has recently been reformulated by Shaw and Bercaw[2], who also report some experimental results on *Drosophila* which they believe to support it. By analogy with chemical reactions, they assume:

$$dy/dt = -ky^n \qquad (1)$$

where y is a 'longevity substance', such that when y falls to a final value y^f the animal dies; k is a constant which depends on the temperature. They are at some pains to show that if an individual is kept for a time x at a low temperature and is then transferred to a higher one, its age at death, l_3, is given by

$$l_3 = l_2 + x(1 - l_2/l_1) \qquad (2)$$

where l_1, l_2 are the life-spans at the low and high temperatures respectively. From this they conclude that if in fact l_3 is found to be a linear function of x, this will support the idea that ageing is due to a simple temperature-dependent process of the kind described in equation (1). They describe an experiment in which male *D. melanogaster* were kept for varying periods at 25° C and then transferred to 29° C. In this experiment they found l_3 to be a linear function of x.

The first point to be made is that equation (2) follows immediately from much more general conditions than those assumed by Shaw and Bercaw. All that is required is to suppose:

(1) Individuals kept at two different temperatures pass through an identical series of states, $a_0\ a_1 \ldots a_r \ldots a_n$, and die when they reach the terminal state a_n; and (2) the time taken to pass from any one state to the next, $a_r \rightarrow a_{r+1}$, at the higher temperature bears a constant ratio to the equivalent time at the lower temperature; if so, clearly the ratio is l_2/l_1.

With these assumptions, suppose that an individual spends a time x at the lower temperature and (l_3-x) at the higher, dying at age l_3. It does not matter how these periods are broken up; for example, the individual might live at the higher temperature first, or spend alternate days at the high and low temperature. Then:

$$l_1 = x + (l_3 - x)l_1/l_2$$

which is the same as equation (2). Thus observational agreement with this equation would not support any particular equation describing the ageing process, but only the very general conditions set out here. By the 'rate of living' theory, therefore, I mean the theory that these conditions are at least approximately satisfied. Such a theory can be tested by an observational check of equation (2).

Unfortunately, Shaw and Bercaw have not established that their observations agree with this equation. They did not measure l_1, the life-span at 25° C, so it is impossible to tell whether the graph of l_3 against x does or does not have the expected slope, although from other work on *D. melanogaster* their slope does seem to be about right.

Finally, they appear to be unaware that a number of experiments[3–5] had previously been published in which the rate of living theory was tested by keeping *D. subobscura* for varying periods at different temperatures. These experiments showed:

(1) Flies kept first at a high temperature and then transferred to a lower one die at the same age as do flies kept continuously at the lower temperature (this statement is only strictly true of males and ovariless females, since the life-span of normal mated females is increased by a preliminary period at a high temperature).

(2) If flies are kept first at a low temperature and are then transferred at various ages to a higher one, then initially their expectation of life at the high temperature is reduced by one day for every day spent at the lower temperature, until the expectation of life at the high temperature has fallen to approximately half its initial value in young flies. Subsequently the expectation of life at the high temperature does not alter substantially with increasing age at the low temperature.

These results are clearly incompatible with the rate of living theory. To explain them, Clarke and Maynard Smith[4,5] put forward what I shall call the threshold theory (Fig. 1*B*). The essential feature of this theory is that if at a lower temperature an individual starts to die when it reaches a state a_n, then at a higher temperature a similar individual will start to die at an earlier state a_r. In more detail, it is assumed:

(1) The life-span is divided into two phases, 'ageing' and 'dying'.

(2) The rate of the ageing process is approximately independent of temperature. It continues until the 'vitality' of the individual has fallen to a threshold-level below which the individual can no longer maintain itself at the temperature at which it is living. This threshold is higher at higher temperatures, so that individuals which can maintain themselves at a low temperature may be unable to do so at some higher temperature.

(3) In individuals whose vitality has fallen below the threshold appropriate to the temperature at which they are living, a second process, 'dying', commences and terminates in death. This dying process is temperature-dependent in its rate, and, provided it is not allowed to terminate in death, can be reversed at lower temperatures.

The evidence supporting these assumptions has previously been published. But the results reported by Shaw and Bercaw, although they may not support the rate of living theory, are incompatible with our finding that the rate of ageing is approximately independent of temperature. Although it is conceivable that there are different mechanisms of ageing in the two species of *Drosophila*, this does not seem likely. It therefore seemed

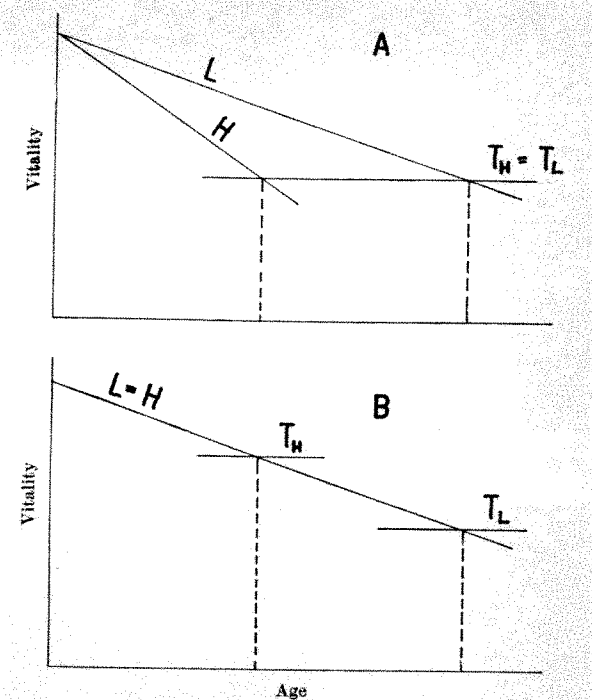

Fig. 1. *A*, the 'rate of living' and *B*, the 'threshold' theories of ageing. In both theories ageing is supposed to lead to a decline in 'vitality' with chronological age, until a threshold is reached, when the individual dies, or starts to die. *L,H* represent the decline in vitality at low and high temperatures respectively; T_H, T_L represent the threshold-levels at low and high temperatures respectively

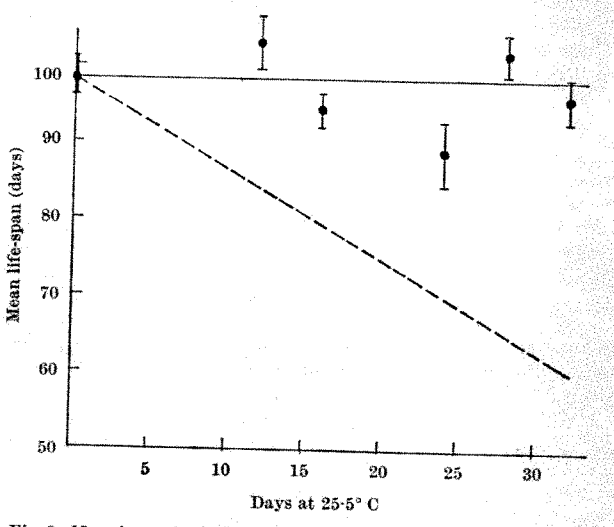

Fig. 2. Mean longevity in days of male *D. subobscura* kept first at 25·5° C and then at 20° C, as a function of time spent at 25·5° C. ●, Observed values; full line, expectation according to threshold theory; broken line, expectation according to rate of living theory

desirable to perform a further experiment to decide between the two theories; this seemed all the more necessary because, in the absence of evidence to the contrary, it is only natural to assume that the rates of ageing processes would be temperature-dependent. At the same time an opportunity has been taken to meet a criticism made by Strehler[6] of our earlier experiments. Strehler argues that in those experiments in which flies were kept first at a high temperature and then transferred to a lower one, the initial temperature, 30·5° C, was so high that the flies were dying of temperature stress and not of ageing: this criticism does not apply to the experiments in which flies were kept first at a low temperature

and then transferred to a high one, since in some of these experiments 26° C was used as the higher temperature.

An experiment has therefore been performed in which flies were kept first at 25·5° C and then transferred to 20° C. The species can reproduce at both these temperatures, although the former is close to the maximum. F_1 hybrid males between the *B* and *K* inbred lines of *D. subobscura* were raised at 20° C, and afterwards kept, 2 males per vial, in 3 in. × 1 in. diameter shell vials containing food medium. The flies were transferred to fresh food vials every two days, since we have found that this procedure gives more repeatable results than our earlier practice of 4-daily transfers. Flies were kept for four days after emergence at 20° C and then, with the exception of a control group, were transferred to 25·5° C. A group of 110 males which were kept continuously at 25·5° C until they died survived for a mean of 43·1 days at that temperature. Other groups, each consisting of 20 flies, were kept at 25·5° C for 12, 16, 24, 28 and 32 days, and were then transferred to 20° C and kept at that temperature until they died. The mean ages at death, with standard errors, of each of these groups are plotted in Fig. 2 against days spent at 25·5° C. Also shown in Fig. 2 are the expectations according to:

(1) The threshold theory, assuming the rate of ageing to be independent of temperature; on these assumptions, all groups returned to 20° C should die at the same chronological age as the controls, regardless of how long they had previously spent at 25·5° C.

(2) The rate of living theory, that is, equation (2), assuming a mean longevity of 43·1 days at 25·5° C.

The results of the experiment contradict the rate of living theory, and are fully consistent with the threshold theory suggested in earlier papers.

Secretory Activity by the Scolex of *Echinococcus granulosus in vitro*

During recent work on the *in vitro* cultivation of the hydatid organism, *Echinococcus granulosus*, observations were made on living 35-day-old strobila freshly removed from the intestine of dogs. Strobila were examined as quickly as possible after autopsy on a warm stage in hydatid fluid or Parker's 199 medium. The scolex showed a very marked activity, one phase of which was characterized by the rostellum region being expanded to its limit—a process resulting in the hooks being raised to form an anterior disk (Fig. 1). This phase may be only momentarily observed for it rapidly changes to one in which the hooks are lowered. This represented a picture of the behaviour pattern of the *Echinococcus* scolex not evident from text-book illustrations, which appear to be based on fixed specimens.

Continual high-power *in vitro* observations of the living scolex has revealed a previously undescribed phenomenon—the secretion of small viscid droplets into the medium from the hook region (Fig. 2). This phenomenon was peculiarly difficult to observe due to the activity of the scolex, but once seen was found repeatedly in many specimens from different dog hosts; the precise site of secretion was not observed. The phenomenon has not been found in strobila earlier than 32-days' development in the dog, and the appearance of the secretion may be related to the metabolism of the later stages of maturation only. Detailed cytological examination of the rostellar region of the scolex[1] has revealed the presence of a group of cells, lying just beneath the anterior tip of the rostellum apparently not figured in early morphological accounts. These cells contained droplets from which the secretions have clearly originated. The existence of gland cells in the scolices of some cestodes[2] has been described; but active secretion from the cestode scolex—nor indeed from any other region of a cestode—does not appear to have been observed or reported. It may prove to be a common phenomenon and may have implications necessitating a revision of our concept of cestode physiology.

Figs. 1 and 2. (1) Scolex of living *Echinococcus granulosus* freshly removed from the dog intestine showing characteristic expansion of rostellar region (electronic flash microphotograph); (2) anterior tip of rostellum of living *Echinococcus granulosus* showing release of a secretion droplet (electronic flash microphotograph)

The nature and possible function of this secretion from *E. granulosus* can be only a matter of speculation at this stage and these questions are being further investigated. In view of the close contact of the scolex with the intestinal mucosa[1], the secretion may be important from the immunological point of view, and for this reason, especially, warrants further investigation.

VETERINARY SCIENCE

Nicotinamide Adenine Nucleotides in Ovine Liver

A knowledge of the levels of nicotinamide adenine nucleotide coenzymes in ruminant liver may be of value in understanding the ætiology of bovine ketosis and ovine pregnancy toxæmia. In particular, the possibility that a deficiency of the reduced form of the dinucleotide phosphate ($NADPH_2$) may be associated with the hyperketonæmia which is characteristic of these metabolic disorders has been suggested by several workers[1–4]. Because $NADPH_2$ is an essential cofactor for fatty acid biosynthesis[5] a deficiency of it would result in impaired lipogenesis and consequently an increased ketogenesis[6,7].

There are few reports in the literature, if any, of the measurement of nucleotide coenzyme-levels in biopsy

samples of ovine liver or of the rates of hepatic $NADPH_2$ formation. The purpose of this communication is, therefore, two-fold: (1) to offer data which indicate the similarity in coenzyme levels of pregnant ewe and rat livers, the rat being taken as a typical non-ruminant; (2) to show that the hyperketonæmia of undernourished ewes is not apparently accompanied by a significantly reduced capacity to form $NADPH_2$ compared with well-nourished control animals.

A slight modification of the enzyme-spectrophotometric method of Holzer *et al.*[8] was used for the assay of either oxidized or reduced forms of the coenzymes in liver biopsy specimens taken from normal pregnant ewes. Results so obtained showed wide variations, and recently it has been found more convenient to use the sensitive and reproducible enzyme-colorimetric method of Slater and Sawyer[9] for the assay of both oxidized and reduced forms in a single biopsy specimen weighing approximately 400 mg. Average nucleotide coenzyme-levels for pregnant ewes estimated by the Holzer method are given in Table 1. The same relative distribution of oxidized and reduced forms was observed as in rat liver, but levels of NAD and NADP were higher. The concentration of $NADPH_2$ was never found to be very low so that apparently the ewe is not especially prone to a deficiency of this cofactor later in pregnancy. Assays made on livers of two similar post-parturient ewes using the enzyme-colorimetric method are given for comparison. Although total amounts of nucleotide so estimated were comparable with values obtained for pregnant ewes by the Holzer method, $NADPH_2$-levels were somewhat elevated. Results obtained for the rat using the same method compared well with Dr. T. F. Slater's own values for his laboratory strain of rat.

Table 1. NUCLEOTIDE COENZYME-LEVELS IN OVINE AND RAT LIVERS

Species	Physiological status	Mean nucleotide content (μg/g fresh liver) (Range of values) (No. of animals)				Method of assay*
		NAD	$NADH_2$	NADP	$NADPH_2$	
Ewe	3–4 wks. pre-partum	482 (258–628) (6)	51 (35–106) (4)	60 (33–113) (3)	183 (162–347) (4)	*H*

Table 2. $NADPH_2$-FORMING ENZYME REACTIONS IN THE LIVER OF THE PREGNANT EWE

Enzyme activities were assayed spectrophotometrically in the supernatant fraction obtained from a 1 : 8 homogenate in 0·15 M potassium chloride by centrifuging at 4,000*g* for 1 h at 0° C. 1 unit of enzyme activity = quantity of enzyme producing 10 mμmoles $NADPH_2$/min at 20° C.

Enzyme assayed†	Well-nourished (control) ewes		Under-nourished (hyperketonæmic) ewes*		Statistical significance of difference between groups
	Days pre-partum	Activity (units/g fresh wt.) (No. of biopsies)	Days pre-partum	Activity (units/g fresh wt.) (No. of biopsies)	
ICD	13·6 ± 2·26	389 ± 22·1 (9)	13·2 ± 0·81	404·6 ± 36·2 (9)	None
G6PD	12·4 ± 2·33	17·1 ± 1·60 (10)	13·2 ± 0·81	18·2 ± 1·80 (10)	None
6PGD	12·4 ± 2·33	18·5 ± 5·12 (10)	13·2 ± 0·81	15·7 ± 8·28 (9)	None
		[Mean values ± *S.E.M.*]			

* Mean plasma concentrations at 13 days pre-partum:
Glucose — Controls 62 m/100 ml.; Hyperketonæmic 48 m/100 ml.
NEFA (non-esterified fatty acids) — Controls 990 μequiv./l.; Hyperketonæmic 1,700 μequiv./l.
Ketone bodies at levels of more than 10 mg 'acetone'/100 ml. were detected in all undernourished ewes.

† Isocitrate dehydrogenase (ICD) by the method of Ciotti and Kaplan 1951) (ref. 10). Glucose-6-phosphate dehydrogenase (G6PD) and 6-phosphogluconate dehydrogenase (6PGD) by the method of Glock and McLean 1958) (ref. 11).

No values have so far been obtained for liver nucleotide concentrations in pregnancy toxæmia but it is hoped to do so using the Slater and Sawyer method when cases become available to us. Observations, to be published in detail elsewhere, on levels of $NADPH_2$-generating enzymes in liver homogenates obtained from hyperketonæmic pregnant ewes (not exhibiting clinical symptoms) are, meanwhile, of interest. These results indicate that there is probably no serious lack of $NADPH_2$ in hyperketonæmia as judged by the *in vitro* rate of formation of this cofactor in the *iso*citrate dehydrogenase, the glucose-6-phosphate dehydrogenase and the 6-phosphogluconate dehydrogenase reactions measured under optimal conditions in livers of these animals (Table 2). Until the direct estimation of nucleotide concentrations has been made in liver samples obtained from clinical cases of pregnancy toxæmia it is impossible to say for certain whether or not $NADPH_2$-deficiency is an important feature of this metabolic derangement, but the experimental results presented here show that $NADPH_2$-levels are not normally very low late in pregnancy. Moreover, in hyperketonæmia induced in the normal pregnant ewe by dietary restriction, the capacity of the liver to form $NADPH_2$ is not significantly diminished.

Effects of Œstrogen on Fertility in Ewes

IN a recent experiment[1] daily injection of 128 and 32 μg of stilbœstrol, prior to, and during, mating reduced fertility in Merino ewes almost to zero. Some circumstantial evidence also suggested that even 8 μg might result in reduced conception percentages and proportions of multiple births. Since intakes of plant œstrogens greater than the equivalent of 8 μg stilbœstrol (assayed by uterine weight in ovariectomized ewes) could be common in sheep-grazing pastures containing subterranean clover or red clover[2,3], it seemed to us important to assay the effects of such doses. Accordingly three groups of about 90 ewes were injected for six weeks, thrice weekly, with 1 ml. peanut oil containing the equivalent of 0, 8 μg and 16 μg stilbœstrol dipropionate (May and Baker) daily. Injections commenced on February 27, 1963. Rams were introduced on March 20 for three weeks. Vasectomized rams were kept with the ewes for a further three weeks. Matings were recorded with the aid of SIRE-SINE harness and crayon.

The ovaries and uteri were examined by laparotomy of those ewes which were found non-pregnant by vasectomized rams, and after slaughter in those judged pregnant. The results are summarized in Table 1.

Table 1. Reproductive Status of Ewes treated

	Level of œstrogen per day		
	0	8 μg	16 μg
Ewes alive	92	91	87*
Not mated	6	7	10
No. services	88	94	85
% conceptions	75	59	42
No. non-pregnant	26	36	51
% Non-pregnant, non-return	4	25	41

* 2 ewes died during the experiment.

Substantial differences between treatments were found in conception percentage and in the percentage of ewes which, although not pregnant, did not return to service within 3 or more weeks after mating.

Some further effects of stilbœstrol were evident from the examination of embryos and ovaries of the pregnant ewes, as shown in Table 2.

Table 2. Multiple Pregnancies and Corpora Lutea in Pregnant Ewes

	Level of œstrogen per day		
	0	8 μg	16 μg
No. pregnant	66	55	37
No. twin pairs	12	5	0
Single corpora lutea	47	50*	35*
Two corpora lutea	19†	5	1
Ovulation-rate	1·29	1·09	1·03
% pregnant, excluding those with two corpora lutea	64	59	41

* One of these scored as zero corpora lutea.
† One of these scored as single corpus luteum.

From these results it is evident that stilbœstrol, administered during mating even at relatively low doses, decreased conception percentages, and affected the œstrous cycle so that many ewes, although not pregnant, did not exhibit œstrus. Moreover, the ovulation rate was considerably reduced, resulting in decreased multiple pregnancies.

The decreased conception percentage was not a result of reduced probabilities of at least one conception associated with decreased multiple ovulation. Of 25 double ovulations observed 16 produced twins. If p is the probability of fertilization of an ovum, and if this is independent of other fertilizations, p is estimated as 0·8. The probability of neither of two ova being fertilized is then 0·04. Therefore the number of non-fertilized double ovulations may be neglected without serious bias. Removing all cases of multiple ovulation from our data, the percentages of pregnancies, shown in the last line of Table 2, are seen to differ to an important extent.

The reduced conceptions, and proportions of multiple pregnancies, are consonant with results reported from ewes mated on red-clover[4,5] and lucerne[6]. It seems likely that many cases of unsatisfactory fertility in sheep, especially those grazed on pastures containing appreciable quantities of red or subterranean clovers, could be caused by relatively small intakes of œstrogen during mating. Doses such as these are unlikely to be associated with permanent effects[7], obvious derangements of mating behaviour, or pathological changes in genitalia. Yet their econonic consequences could be far more serious than those reported for prolonged ingestion of relatively large doses other than during the mating period.

CYTOLOGY

Trisomy of Autosome 16

So far as we are aware, true trisomy of autosome 16 (Denver classification) has not previously been reported, accordingly we wish to record the following case.

The patient is a female æt. 59 with certain multiple congenital abnormalities. Her buccal smears on two separate occasions gave 34 and 46 per cent single Barr bodies. The peripheral blood cultured by the technique of Moorhead *et al.*[1] gave the chromosome pattern presented in Table 1 and Fig. 1.

Table 1

Chromosome No.	43	44	45	46	47	>47	Total
Cell count	1	1	1	4	91	2	100

The following statistical analysis revealed that the 47's were trisomic for 16: variance of arm ratios (long arm/short arm) of the 3 autosomes 16 in the patient compared with each other was not significant at the 5 per cent level. Variance of arm ratios of these 3 autosomes compared with a control series was not significant at the 5 per cent level (F ratio 1·42, degrees of freedom 35, 49). Confidence limits based on this variance also indicated that the extra chromosome was unlikely to be an isochromosome of X. This was further confirmed by comparing the total length of this chromosome to the short arm of the X-chromosome.

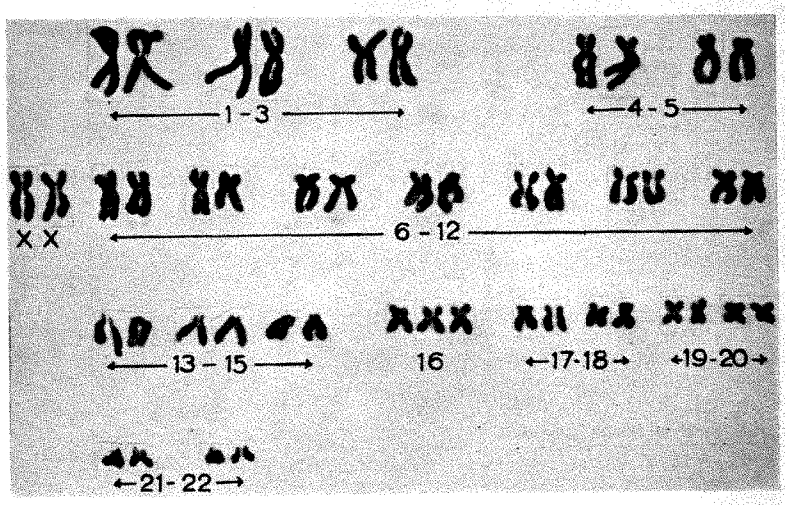

Fig. 1. Karyotype of a typical spread (case 62/750; cell 66)

(F ratio 3·19, degrees of freedom 11, 11, significant at the 5 per cent level.)

Student's t test on means of arm ratios demonstrated that the extra chromosome does not belong to the 17–18 group. ($t = 14·34$ degrees of freedom 25, highly significant at the 0·1 per cent level.) These findings appear to establish that this is in fact trisomy of 16, is unrelated to either the 13–15 or 17–18 groups, and is not an isochromosome of X.

We thank Dr. Heaton-Ward for permission to publish this case and Mr. G. M. Clarke for his help with the statistics. We also thank the Ethel Showering Fund for defraying some of the expenses.

ENTOMOLOGY

Procedure for Rearing Houseflies

THE various methods and media used for rearing houseflies[1] each give results considered satisfactory by the individual workers or laboratory, but no rearing procedure is yet accepted as standard. The Chemical Specialties Manufacturers' Association rearing medium and procedure[2] are often accepted in North America but do not appear to be used elsewhere. The rearing procedure evolved in this laboratory[3] has since been modified in the various ways described in *a–d* below, and is now probably simpler and easier than any previously described.

The modifications of the previously described procedure[3] are: (*a*) A 2-in. diameter hole is added to the bottom lid of each cylindrical cage. This accommodates a polythene feeding cup of the same diameter and about 1·5 in. high. These cups are conveniently made by cutting away the upper portion of a 6-oz. polythene bottle. (*b*) The milk-sugar-water food fed previously often sours and requires frequent renewal. As a simpler procedure, each cage, containing up to 1,500 adult flies, is now supplied with approximately 200 ml. of 2·5 per cent sugar solution in the feeding bottles and approximately 25 g dry food in the feeding cups. Cages are charged in this way when pupæ are added for emergence; thereafter the food is changed weekly or when the supply nears exhaustion, except that flies intended for insecticide testing have both sugar solution and solid food renewed two days prior to the insecticide tests. Flies intended for insecticide testing are fed dry white cane sugar in the feeding cups. Those which provide eggs for further rearing are fed a dry mix containing equal parts by weight of cane sugar and dried whole cream milk powder to which are added 10 per cent dried yeast and 0·1 per cent cholesterol. These proportions are arbitrary, and no attempt has yet been made to establish to what extent proportions could be varied or components eliminated. Cholesterol is added as a precaution against inferior egg hatching[4]. A synthetic diet for adult houseflies is available[4]; its adoption could be a further step towards a standardized rearing procedure. (*c*) The breeding medium now used comprises equal parts dry weight of absorbent tissue paper and dried whole cream milk powder to which is added 5 per cent of dried yeast, and 2·1 ml. water/g dried mix. Each rearing jar receives rearing medium from 75 g of dry mix and this is seeded with 0·4 ml. of eggs to produce 1,300–1,500 pupæ in 7 days at 25° C. (*d*) In the earlier procedure[3] the absorbent tissue was soaked for 30 min to facilitate pulping before the dry mix was worked into the wet tissues. It has also been suggested that the tissues be shredded into pieces about an inch long[5]. In the present procedure the dry tissues are disintegrated in a cutting mill run at 3,000 r.p.m., all material passing a 12 mesh to linear in. screen before leaving the mill. The final product is a loose flock, without obvious particles of sheet paper. On mixing the paper flock with the dry components of the medium and adding the water the materials aggregate in large discrete crumbs. This wet material is then easily transferred to the rearing jars, is uniformly distributed by slight shaking and is then lightly tamped prior to addition of eggs.

The last of these modifications has transformed medium preparation from a tiring and time-consuming task to a simple instant mix easily effected with a glass rod. The physical consistency of the wet mix allows excellent penetration by the growing larvæ. The usual fly culture odours are noticeably absent, and there have been no cases of mould or bacterial invasion leading to the revolting 'cheesy' or rotten odour sometimes developed with the mashed paper medium. Pupation occurs in the medium. Pupæ are easily separated by flotation, and, because there is no entanglement, with incompletely macerated paper almost all pupæ are recovered.

Table 1. EFFECTS OF SUBSTITUTING DRIED SKIM MILK FOR DRIED WHOLE CREAM MILK AND OF ADDED CHOLESTEROL ON THE SUITABILITY OF THE STANDARD DIET

Rearing medium	No. of trials	Average values of rearing unit			
		No. of pupæ	Total weight of pupæ (g)	Pupal weight (mg)	Total eggs laid (ml.)
Normal	8	1,374	21·8	16·2	2·6
Skim milk		1,531	16·8	11·1	1·2
S.E. of mean		49·4	0·84	0·52	0·37
Significance		Sign.	H. Sign.	V. H. Sign.	Sign.
Normal	14	—	20·8	15·4	2·9
+1·0% cholesterol		—	20·7	15·4	2·8
S.E. of mean			0·70	0·37	0·16
Significance			N.S	N.S.	N.S.

The overall improvement resulting from this simple mechanical preparation of the paper has remarkably simplified rearing procedures, and it is suggested that the medium described here might well serve as a simple and approximately standard rearing medium until fully defined diets and conditions are available. Further, the dry medium could probably be mixed in bulk and stored or the wet mix prepared and deep-frozen until required, an expedient which is frequently used in this laboratory.

Two other variations have failed to effect improvements in the breeding medium. First, substitution of the cheaper dried skim milk for dried whole cream milk increased the number of pupæ per culture but so markedly decreased the average weight of individual pupæ that the biomass per culture unit was decreased. Further, the skim milk-reared flies took longer to come to egg production and the total yield of eggs per rearing unit was less than half that of those reared on the whole milk diet. Information for eight rearings is summarized in Table 1. Secondly, when cholesterol amounting to 1·0 per cent of the dry weight of yeast and milk powder was added to the medium[6] and compared with the normal rearing medium (Table 1) there were no real differences in numbers of pupæ reared, average weight of pupæ, initial egg production or the total egg yield.

Response to Movement by *Formica polyctena* Forst.

ANTS of the *Formica rufa* group often overlook suitable prey if it does not move[1] and often attack insects not normally preyed upon if they perceive movement[2]. The following experiment was designed to obtain more accurate information on the role of prey movements in the searching behaviour of worker ants.

A small spindle was placed through the centre of the floor of a 1 m² forage area of a colony of 3,000 workers of *Formica polyctena* Forst. A portion of the spindle below the floor was fitted with vanes, allowing the spindle to be rotated by air blown through a rubber tube from a small aspirator bulb. The portion of the spindle above the floor was fitted with either a small white paper flag painted black on one side, or a small drum with black and white vertical stripes. The flag, because it was off-centre, caused a vibration when rotated. When in use these two objects were covered with one of the following: (1) an opaque cover that prevented the

ants from seeing the object or detecting any direct air currents; (2) a double 30-mesh copper screen which did not completely stop air current, but minimized the possibility of the ants seeing movement; or (3) a glass vial which allowed the ants to see the movement but prevented the detection of air currents. The tests were made by rotating the drum or flag once every five seconds for ten-minute periods. The number of ants attracted to within a 5-cm radius of the spindle during this period was compared with the number of ants passing through the same area during the 10 min both before and after the test. The number of ants in the initial control varied from 14 to 34, depending on the number foraging. In addition, the effect of smell was tested by placing freshly dissected cutworms, a normally acceptable food, under a small screen. The results of three repetitions of each test are given in Table 1.

Table 1. Ratio of the Numbers of Ants responding to Rotation of a Flag or Drum. A 10-min Period before the Test = 1

	10-min test period	10-min period after test
(*A*) Rotating flag		
(1) Opaque cover	2·2	1·3
(2) Screen cover	5·6	1·5
(3) Glass cover	7·3	1·7
(*B*) Rotating drum		
(1) Opaque cover	0·1	0·3
(2) Screen cover	0·8	0·4
(3) Glass cover	9·4	3·9

The foregoing results show that vibration and visual movement are the main factors in attracting these ants to their prey. All tests using the flag excited most of the ants in the area, but when the object was completely covered (*A*1) they had difficulty in locating the source of the disturbance. Nevertheless, the response was significant at the 0·02 per cent level. The fact that a highly significant response was obtained from the screen and flag, but not from the screen and drum, indicates the screen was a good visual barrier and the response from the flag (*B*2) was caused by vibration. A highly significant response was obtained from both tests in which the workers could see the object (*A*3 and *B*3). No response was obtained from the tests with dissected cutworms.

GENETICS

Differential Mutagenic Activity of *l*(+) and *d*(—) Diepoxybutane

The mutagenic activity of diepoxybutane (1 : 2,3 : 4-butadiene dioxide) has been investigated in several biological systems[1–3]. In *Neurospora*, its ability to induce back mutations at the adenineless locus was found to be about twenty times higher than with X-rays[1]. On the other hand, its chromosome-breaking activity is high for both higher plants and animals[3–5]. In this respect, this difunctional compound is about 150 times more efficient than the monofunctional corresponding ethylene oxide. Two isomers of this compound were synthesized by Feit[6]. The experiments recorded here were designed to test if the two compounds have similar activity in both producing mutations and chromosome aberrations.

A mould, *Penicillium multicolor* G-M and P, was selected for checking mutation rate. Treated conidia were plated on complete Czapek–Dox medium, and all kinds of hypomorphic clones were recorded and isolated for further control of stability. No significant difference in toxicity was observed (Fig. 1). In contrast, it was found that

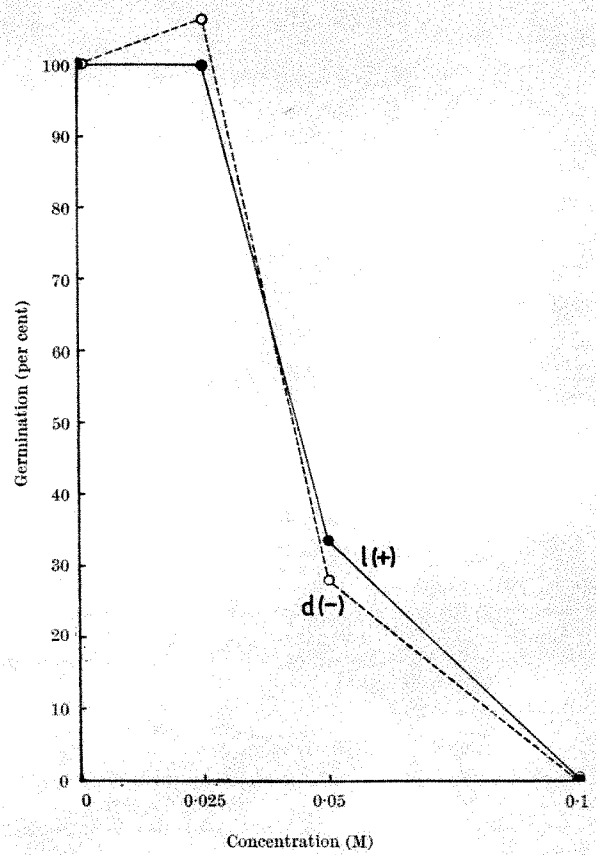

Fig. 1. Toxicity of isomers *l*(+) and *d*(−) of diepoxybutane in *Penicillium multicolor* (percentage of control)

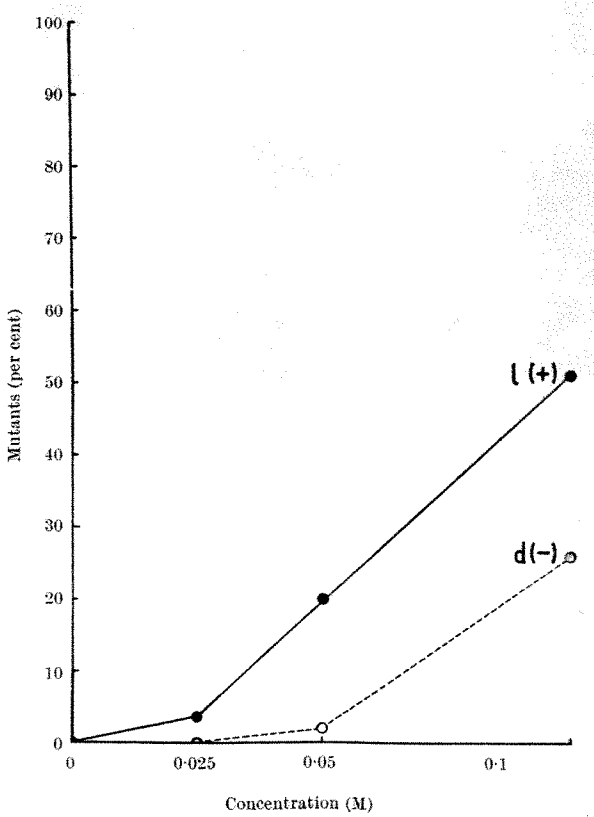

Fig. 2. Mutation-rates with isomers *l*(+) and *d*(−) of diepoxybutane in *Penicillium multicolor*

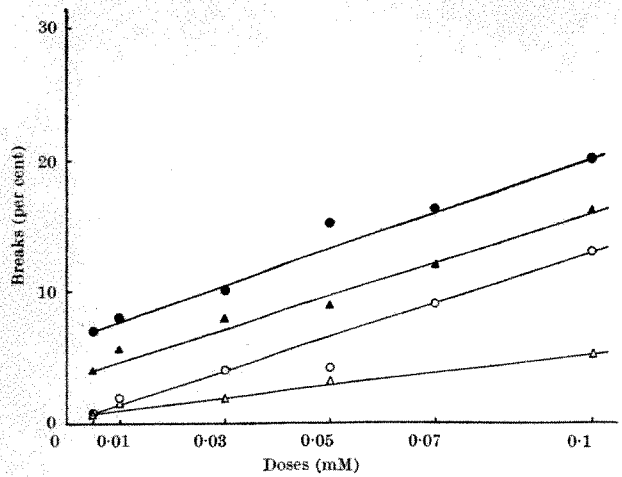

Fig. 3. Percentages of chromosome breaks induced with isomers $l(+)$ and $d(-)$ of diepoxybutane in *Vicia faba*

$l(+)$ {●, B $B + SR$ ▲, B $d(-)$ {○, $B + SR$ △, B

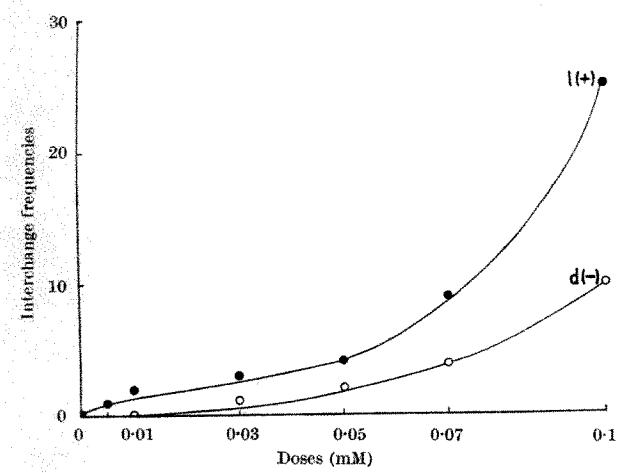

Fig. 4. Frequencies of chromosome interchanges induced with isomers $l(+)$ and $d(-)$ of diepoxybutane in *Vicia faba*

mutation rate is constantly higher for the $l(+)$ isomer. A 0·1 M for 45 min of $l(+)$ dose induced 2 times more detectable mutant clones (Fig. 2). In this organism, this dose is as efficient as 5×10^4-r. X-rays for $l(+)$ and $2{\cdot}5 \times 10^4$-r. X-rays for $d(-)$. In order to extend these results to chromosome breakage, dry broad bean seeds were treated at increasing doses. The $l(+)$ isomer was shown to produce more chromosome aberrations than $d(-)$. In Fig. 3 it can be seen that the main part of this effect is due to the increase of breaks rather than sister unions. Whether this higher break frequency originated from a decreased restitution process cannot yet be stated.

Fig. 4 clearly shows that the interchange frequency is also higher with the $l(+)$ compound. For both $l(+)$ and $d(-)$, the dose-effect curve is two hit for interchanges whereas it is one hit for breaks (Fig. 3).

These curves can be compared with those obtained with X-rays. The localization of chromosome aberrations was not observed to be different for $l(+)$ and $d(-)$ compounds. In contrast with X-rays a majority of aberrations is localized within the cephalobrachial chromosomes and all the isomers show an affinity for heterochromatic segments of the genome.

At this stage of the research, it can only be supposed that the differential activity of the isomers has a chromosomic origin. In this case, the toxicity of the compounds would not be mainly chromosome dependent. Other tests should be designed at specific loci to check whether this assertion can be extrapolated to point mutations.

We thank Dr. W. Feit (Ballerup), who provided the compounds, and Dr. L. Ehrenberg (Stockholm) for valuable suggestions.

Male Sterility for Increased Outbreeding in Populations of Barley

In recent years several interesting mechanisms have been investigated which enable many plant species to maintain a mixed mating system with its variable proportions of outbreeding and inbreeding adaptively adjusted to the optimal requirements of recombination potential, hybridity and reproductive economy[1–3]. In the predominantly self-fertilized species such mechanisms seem to be of particular evolutionary significance. Using a theoretical model, Jain[4] showed that male sterility factors occurring in their populations might be favoured for an effectively increased rate of outcrossing on the male-sterile individuals. The adaptive role of cytoplasmic male sterility in the case of gynodioecious species was discussed earlier by Lewis[5]. The composite cross-bulk populations of barley in which a recessive male sterility gene (*ms*) has been introduced to facilitate continued recombination[6] provide suitable material for examining the consequences of Jain's model. In this communication an analysis of two such populations is briefly discussed in relation to the regulation of breeding system.

The observed proportion of male-steriles (*ms ms*) in various successive generations of the *C.C.XIV* and *C.C.XV* populations of barley are given in Table 1. From the results on percentage seed-setting on the male-sterile plants their probability of outcrossing (kt) was found to be 0·42 and 0·36 in the two populations respectively where the amount of outcrossing (t) in the absence of *ms ms* individuals was estimated to be 0·01–0·02 (ref. 7). The selection coefficients were estimated under two alternative sets of values, namely, (1) *Ms Ms* = *Ms ms*, x_a; *ms ms*, 1; or (2) *Ms Ms*, x_b; *Ms ms* = *ms ms*, 1 ($0 < x < 1$). The *ms ms* class being poorer in seed set, the latter set thus requires heterozygote advantage over both the homozygotes. Estimates of x_a and x_b that suggest an intense selection differential among the three genotypes at this locus are given in Table 1. In both populations the frequency of *ms ms* (Q) decreased with advancing generations except for a notable increase in the F_6 generation. However, their rate of diminution is clearly much lower than would be expected without selection. In the present material the initial selective advantage of male sterility gene seems to be eventually outweighed by the lower fertility of male-steriles. In view of the low values of selection coefficient, perhaps heterozygote advantage at several other loci may also have to be invoked for the maintenance of *ms* gene in such populations.

In order to determine the extent of increased outbreeding due to a male sterility factor, a coefficient (t') measuring the rate of outcrossing in populations such as *C.C.XIV* and *C.C.XV* may be defined as:

$$t' = t(1-Q) + ktQ$$

A point to note is that adjustments needed in the two terms $t(1-Q)$ and ktQ for the absence of pollen on *ms ms* plants counterbalance each other. Now, as shown by

Table 1. Estimates of the Relative Frequency of Male-Steriles (Q %) and the Selection Coefficient (x)*

Generation	CC XIV Q	CC XIV x_a	CC XIV x_b	CC XV Q	CC XV x_a	CC XV x_b
F_2	26·38			26·07		
		0·634	0·278		0·848	0·680
F_3	28·36			24·06		
		0·450	0·750		0·549	0·680
F_4	18·69			16·40		
		0·194	0·070		0·243	0·253
F_5	28·33			21·25		
		0·514	0·920		0·410	0·800
F_{10}	5·16			6·19		
		0·385	0·368			
F_{13}	6·17					
		0·770	0·891			
F_{14}	2·08					
		1·000	1·000			
F_{15}	Less than 1·00					

* Selection coefficients were estimated for each time interval between various generations so as to give the best fit to the observed frequencies.

Table 2. Some Theoretical Values of Q, t' and H at Equilibrium

Q	$kt = 0·42$ t'	$kt = 0·42$ H	$kt = 1·00$ t'	$kt = 1·00$ H
5·0	0·040	0·038	0·069	0·065
10·0	0·060	0·056	0·118	0·106
20·0	0·100	0·091	0·216	0·178

Wright[8], the panmictic index $(1-F)=\frac{2t'}{1+t'}$, and at equilibrium the expected amount of heterozygosity (H) at a locus with gene frequencies (p, q) is simply given by $H=2pq(1-F)$. Table 2 gives numerical examples of this relationship among Q, t' and H for two different values of kt (0·42 and 1·00) and $p=q=0·5$, $t=0·02$. Thus, for Q as large as 10·0–20·0 the amount of increase in outbreeding as well as in the levels of heterozygosity is large enough to be of adaptive significance, as postulated by Jain[4], and this contribution is proportional to k, the probability of outcrossing on male-steriles. The population genetics of such devices controlling the breeding system of a species is indeed likely to direct attention of many more investigators handling natural as well as experimental populations of inbreeding species. The adaptive maintenance of an outbreeding factor in such species has important bearing also on their controlled breeding methods.

SOIL SCIENCE

Relationships between Mycostasis and Free Monosaccharides in Soils

Investigations of the mycostatic factor in British soils[1] have shown that mycostasis is reduced and finally masked by the addition of increasing concentrations of glucose to the soil. It has further been shown[2] that seasonal variation in mycostatic activity in British soils could be closely correlated to the level of reducing substances present: a high level of mycostatic activity corresponding to a low level of reducing substances while an increase in the level of reducing substances resulted in a low level of mycostasis.

Reducing substances were estimated as glucose equivalents on water extracts of pine forest humus layer (A horizon) from North Wales obtained by bubbling oxygen-free nitrogen gas through a soil/water mixture. After centrifugation, substances other than sugars were precipitated from the supernatant with neutral lead acetate, after which sugars were estimated by Wager's[3] modification of the Shaffer–Hartman method and measured photometrically on a Spekker absorptiometer at 580μ, using Nelson's[4] arsenomolybdate chromogenic reagent.

Qualitative analysis of the sugars present in the soil extracts was carried out chromatographically. 1-kg samples of soil from the A horizon in pine forest in North Wales were sieved through a B.S. 10 mesh and extracted:

(a) By stirring with 0·5 N sodium hydroxide for 48 h; the supernatant siphoned off and acidified with hydrochloric acid to precipitate the humic acids. The solution was passed through animal charcoal, previously treated with 0·1 hydrochloric acid, and the eluate concentrated under reduced pressure at 50° C. The residue was extracted twice with ethanol and finally reduced to dryness under vacuum. The residue was made up in 50 ml. of double distilled water passed through 'Zeo-Karb 225' and 'Deacidite FF' and further concentrated to 2 ml.

(b) By bubbling oxygen-free nitrogen gas through a soil/water mixture for 5 h, followed by centrifugation at 3,000 r.p.m. for 20 min. The supernatant was Seitz-filtered, and the tannins present were precipitated with saturated neutral lead acetate and the solution filtered through Whatman No. 50 filter paper on to sodium oxalate. The precipitated lead oxalate was filtered off and the filtrate concentrated under reduced pressure to 50 ml., after which it was passed through 'Zeo-Karb' and 'Deacidite FF' and finally concentrated to 2 ml.

Chromatograms of the two solutions obtained from (a) and (b) were run on Whatman No. 1 paper against standardized solutions of known monosaccharides in butanol/pyridine/water (6 : 4 : 3) for 48 h at 25° C. The chromatograms were dried, dipped into a solution of silver nitrate in acetone, further dried and sprayed with alcoholic sodium hydroxide. The developed chromatograms were dipped into 2 N ammonia and finally rinsed in sodium thiosulphate/sodium metabisulphite solution.

Chromatograms of the solutions (a) and (b) above showed the presence of ribose, sorbose and galactose together with an unidentified spot of high molecular weight. Similar chromatograms from the extract after hydrolysis with N sulphuric acid showed a decrease in concentration at this spot accompanied by an increase in size and intensity of the spots for ribose and galactose, indicating hydrolysis of an unidentified polysaccharide. Autoclaved soil gave much larger spots for the same three sugars with the addition of a spot with the same R_F value as xylose.

The absence of glucose in the soil solution confirms the findings of Hinson[5], who showed that glucose added to forest soils disappeared very rapidly over the course of a few days, probably due to its utilization by the soil microflora.

Recent work by Nagar[6] has shown that free monosaccharides also occur in American and Brazilian soils, and work is now in progress to establish whether or not free sugars occur in the highly mycostatic soils of Malaya[7].

Our thanks are due to the Forestry Commission for a grant to one of us (D. A. G.) which enabled this work to be carried out.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEMONSTRATOR (with a good honours degree in physics, chemistry, applied mathematics or some branch of engineering) IN FUEL TECHNOLOGY AND CHEMICAL ENGINEERING—The Registrar, The University, Sheffield (July 31).

RESEARCH ASSISTANTS in the following departments: COMPUTING, CYBERNETICS AND MANAGEMENT (in Statistics or Programmed Learning); APPLIED PHYSICS (one in Solid State Physics and one in Metal Physics); CHEMISTRY; CIVIL ENGINEERING AND BUILDING; MECHANICAL ENGINEERING; and ELECTRICAL ENGINEERING—The Registrar, Brighton College of Technology, Richmond Terrace, Brighton 7 (July 31).

LECTURER or ASSISTANT LECTURER (with a degree in agricultural chemistry, biochemistry or physiology, and an interest in human nutrition) IN THE DEPARTMENT OF NUTRITION—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (July 31).

GRADUATE RESEARCH ASSISTANT (qualified for registration for Ph.D degree, and with a special interest in organic chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (August 1).

ASSISTANT EXPERIMENTAL OFFICER (with a degree in science, horticulture or agriculture, or equivalent), for physiological studies on vegetable crops—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 3).

EXPERIMENTAL OFFICER (preferably with experience in at least one branch of spectroscopy) IN SPECTROSCOPY IN THE DEPARTMENT OF CHEMISTRY—The Registrar, The University, Manchester 13 (August 3).

HEAD (highly qualified experienced person) OF THE DEPARTMENT OF BUILDING AND CIVIL ENGINEERING—The Staff Officer, College of Advanced Technology, Gosta Green, Birmingham 4, quoting Ref. 7/63/6 (August 3).

RESEARCH ASSISTANT (with a degree in agriculture) IN CROP HUSBANDRY; and a RESEARCH ASSISTANT (with a degree in zoology) IN AGRICULTURAL ZOOLOGY, for work on the potato crop—The Secretary, The School of Agriculture, West Mains Road, Edinburgh (August 3).

SPECIAL RESEARCH ASSISTANT (with a Ph.D. and interested in the physics of liquids) to Dr. V. I. Little IN THE DEPARTMENT OF PHYSICS, for work on the recoilless emission of gamma-rays from macromolecules in supercooled solution—The Secretary of Council, Bedford College (University of London), Regent's Park, London, N.W.1 (August 5).

TUTORIAL ASSISTANT IN PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (August 6).

GRADUATE RESEARCH ASSISTANT (preferably male, with at least an ordinary degree in a combination of biological subjects, including zoology) TO THE PROFESSOR OF ZOOLOGY AND COMPARATIVE PHYSIOLOGY, for work on the electron-microscopic structure and on the electrophysiology of sense organs—The Assistant Registrar (Science), The University, Birmingham 15 (August 7).

SENIOR LECTURER IN MICROBIOLOGY at the University of the West Indies —The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (August 7).

RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICS, for work on infra-red lasers under Prof. G. F. J. Garlick—The Registrar, The University, Hull (August 9).

SENIOR RESEARCH FELLOW IN CRIMINOLOGY, to work within the Department of Social Studies—The Registrar and Secretary, The Durham Colleges in the University of Durham, 38 North Bailey, Durham (August 9).

EXPERIMENTAL OFFICER IN THE DEPARTMENT OF METALLURGY, to be responsible for the maintenance of X-ray equipment for undergraduate teaching and for research—The Registrar, The University, Manchester 13 (August 10).

INVESTIGATIONAL OFFICER (with a degree or diploma in agriculture, and preferably a knowledge of economics and accountancy) IN THE DEPARTMENT OF AGRICULTURAL ECONOMICS, mainly for the collection and initial processing of the data from farms—The Registrar and Secretary, King's College (University of Durham), 6 Kensington Terrace, Newcastle upon Tyne 2 (August 10).

LECTURER or ASSISTANT LECTURER (with a good degree in chemical or mechanical engineering) IN THE DEPARTMENT OF POLYMER AND FIBRE SCIENCE—The Registrar, Manchester College of Science and Technology, Sackville Street, Manchester 1 (August 10).

RESEARCH ASSISTANTS (2) (with postgraduate experience) IN PLANT PHYSIOLOGY IN THE DEPARTMENT OF AGRICULTURAL SCIENCE, School of Agriculture, to undertake investigations on the physiology of the potato plant—The Registrar, The University, Nottingham (August 10).

SENIOR LECTURERS, LECTURERS, or ASSISTANT LECTURERS IN (*a*) ANIMAL NUTRITION; (*b*) ANIMAL BREEDING AND GENETICS; (*c*) ANIMAL HEALTH (registrable veterinary qualifications essential); (*d*) SOIL MICROBIOLOGY; and (*e*) TREE AND ECONOMIC CROP AGRONOMY at the University of Ife, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 10).

CHIEF TECHNICIAN (with university or equivalent experience) IN THE ZOOLOGY DEPARTMENT, University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 13).

ASSOCIATE PROFESSORS (2) IN VIROLOGY AND BACTERIOLOGY in the Medical School, University of Lagos, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

BIOCHEMIST or CHEMIST (with a good honours degree or equivalent and research experience) FOR THE LIPIDS BIOCHEMISTRY DEPARTMENT—The Secretary, Rowett Research Institute, Bucksburn, Aberdeen (August 15).

LECTURER and an ASSISTANT LECTURER IN THE MECHANICS OF FLUIDS in the Faculty of Science—The Registrar, The University, Manchester 13 (August 15).

LECTURER or ASSISTANT LECTURER (preferably with special interests in hydrology, or economic geography or regional geography of North America) IN GEOGRAPHY at the University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

LECTURER or JUNIOR LECTURER or JUNIOR RESEARCH FELLOW (with a higher degree, some teaching and research experience, and preferably a medical qualification) IN PHARMACOLOGY IN THE DEPARTMENT OF PHYSIOLOGICAL SCIENCES, University of Lagos—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

PULMONARY PHYSIOLOGIST (graduate with honours in physiology with interest in respiratory physiology, and preferably experience of pulmonary function techniques) FOR A PULMONARY FUNCTION UNIT now being established—The Secretary, Glasgow Royal Infirmary, 84 Castle Street, Glasgow, C.4 (August 15).

ASSISTANT LECTURER and a COLLEGE LECTURER (graduates in medicine or pharmacy, and preferably with teaching or research experience in pharmacology or cognate subjects) IN THE DEPARTMENT OF PHARMACOLOGY —The Secretary and Bursar, University College, Dublin, Republic of Ireland (August 17).

HEAD (with high academic qualifications and interested in the developme t of higher national certificate and other courses suited to the needs of the growing chemical industry in the area) OF THE DEPARTMENT OF APPLIED CHEMISTRY—The Principal, College of Technology, Belfast 1, Northern Ireland (August 17).

SENIOR LECTURER or LECTURER IN THERAPEUTICS IN THE DEPARTMENT OF MATERIA MEDICA AND THERAPEUTICS—The Secretary, The University, Aberdeen (August 17).

STAFF TUTOR IN PSYCHOLOGY IN THE DEPARTMENT OF EXTRA-MURAL STUDIES—The Registrar and Secretary, King's College (University of Durham), 6 Kensington Terrace, Newcastle upon Tyne 2 (August 17).

SENIOR RESEARCH FELLOW (with a Ph.D. or equivalent postgraduate research experience) IN PARASITOLOGY IN THE DEPARTMENT OF ZOOLOGY, The Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 18).

ASSISTANT LECTURER (with medical qualifications registrable in the United Kingdom) IN ANATOMY—The Registrar, The University, Manchester 13 (August 24).

LIBRARIAN, grade IV (with at least A.L.A. or London Diploma, and an interest in biology) mainly for cataloguing in a small specialized library—The Establishment Officer, Anti-Locust Research Centre, 1 Princes Gate, London, S.W.7 (August 26).

ASSOCIATE PROFESSOR/SENIOR LECTURER IN MEDICINE at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 30).

POSTGRADUATE SCHOLARSHIP IN PROGRAMMED LEARNING—Dr. E. D. Fraser, Department of Psychology, The University, Old Aberdeen, Scotland (August 30).

READER or SENIOR LECTURER IN MICROBIOLOGY; and a LECTURER IN MICROBIOLOGY at Monash University, Victoria, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia (Australia and London, August 30).

ASSISTANT LECTURER (veterinary surgeon or with a degree in physiology) IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (August 31).

DEPARTMENTAL GRADUATE ASSISTANT (with a degree or equivalent qualifications in chemistry and physics or in either subject separately), to operate a nuclear magnetic resonance spectrometer as a service for all departments in the School of Chemistry—The Registrar, King's College (University of Durham), Newcastle upon Tyne 1 (August 31).

DEPUTY REACTOR ENGINEER (with a university degree in engineering or an equivalent qualification, several years industrial experience, and preferably experience in plant operation) in connexion with the nuclear reactor to be operated jointly by the University of Liverpool and the University of Manchester—The Bursar, The University, Manchester 13 (August 31).

HEAD (with a dental qualification registrable with the South African Medical and Dental Council) OF THE DEPARTMENT OF DENTISTRY AND DIRECTOR OF THE ORAL AND DENTAL HOSPITAL, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1—(South Africa and London, August 31).

LECTURER/ASSISTANT LECTURER (preferably with experience in teaching and research) IN THE DEPARTMENTS OF ANATOMY AND PHYSIOLOGY in the newly established Faculty of Medicine, University of Malaya—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, August 31).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF PHARMACOLOGY—Clerk to the Council, School of Pharmacy (University of London), 29/39 Brunswick Square, London, W.C.1 (August 31).

LECTURER (with higher qualifications in physics or physical chemistry, and preferably research experience in the physics of solid/liquid, liquid/liquid systems or of powders) IN THE DEPARTMENT OF PHARMACEUTICS—The Clerk to the Council, School of Pharmacy (University of London) 29/39 Brunswick Square, London, W.C.1 (August 31).

SENIOR ASSISTANT (with experience of the application of electron microscopy to plant material) IN RESEARCH IN CASUAL MORPHOLOGY AND FINE STRUCTURE IN THE DEPARTMENT OF BOTANY—Dr. H. L. K. Whitehouse, Botany School, The University, Downing Street, Cambridge (August 31).

READER (with general experience in the various branches of microbiology) IN MICROBIOLOGY—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (September 1).

SENIOR LECTURER (with a special interest in physical-organic chemistry, and preferably experience in teaching and capable of initiating independent research; some industrial experience would be an advantage) IN THE DEPARTMENT OF CHEMISTRY—Clerk to the Governing Body, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (September 2).

LECTURER IN MICROBIOLOGY at the University of Western Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 7).

MYCOLOGIST (male, with postgraduate research experience) in the Chamber's Biological and Chemical Research Laboratory, Transvaal and Orange Free State Chamber of Mines Research Laboratories, to lead a team in systematic and ecological studies of fungi occurring in the mines, and in the gold and uranium recovery processes, including a study of fungi growing on timber and other organic materials in the mines,with particular reference to basidiomycetes and possible pathogens—The Officer-in-Charge, South African Scientific Liaison Office, Chichester House, 278 High Holborn, London, W.C.1 (September 7).

CHAIR OF FIBRE SCIENCE IN THE DEPARTMENT OF TEXTILE INDUSTRIES—The Registrar, The University, Leeds 2 (September 16).

READER IN MATHEMATICS (Applied) at Birkbeck College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 16).

CHAIR OF MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (September 30).

PROFESSOR OF MATHEMATICS (either Pure or Applied)—The Registrar, The University, Leeds 2 (September 30).

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree in agriculture and an interest in applied research), for work of an essentially practical nature on the storage and handling of potatoes—The Secretary, Ditton Laboratory, Agricultural Research Council, Larkfield, near Maidstone, Kent.

BACTERIOLOGIST (non-medical, basic grade, with a B.Sc. qualification in biological subjects) IN THE BACTERIOLOGY DEPARTMENT—The Superintendent, Royal Infirmary, Infirmary Road, Sheffield 6.

BIOCHEMIST (basic grade) (with a degree in chemistry or biochemistry, preferably with honours, or an equivalent qualification) IN THE BIOCHEMISTRY DEPARTMENT—Mr. H. Varley, Biochemistry Department, Manchester Royal Infirmary, Manchester, 13.

BIOCHEMIST (with an honours degree in chemistry, an Associate of the Royal Institute of Chemistry, at least two years postgraduate experience in medical biochemistry, and national of, and permanently resident in, Great Britain or the Republic of Ireland) with the Government of Uganda, to be in charge of the Biochemistry Division of the Laboratory services located at Kampala and serving all parts of the country and all races—The Director of Recruitment, Department of Technical Co-operation, 3 Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. RC.205/153/026.

CHAIR OF PHYSICS (other than nuclear physics)—The Secretary, University of Lancaster, P. O. Box 78, County Hall, Preston.

CHAIR OF PURE MATHEMATICS—The Registrar and Secretary, The University, Bristol.

EXPERIMENTAL OFFICER (with distinct skill in experimental organic chemistry and a sound knowledge of chemical theory) IN THE DEPARTMENT OF CHEMISTRY, to carry out research and development work on the controlled oxidation of aromatic compounds and of more complex materials—The Registrar, The Manchester College of Science and Technology, Sackville Street, Manchester 1.

HEAD OF THE BIOCHEMISTRY AND BIOPHYSICS DIVISION—The Director, Arthur D. Little Research Institute, Inivereskgate, Musselburgh, Midlothian.

GEOLOGIST (with a university degree including geology as a major subject, at least six years practical experience since graduation, and preferably experience in engineering geology) IN THE DEPARTMENT OF MINES, Tasmania, for geological investigations in the exploration and development of mineral resources, regional geological mapping, and engineering geology—The Agent-General for Tasmania, 457 Strand, London, W.C.2.

JUNIOR BACTERIOLOGIST (qualified experienced male or female technician, or graduate), for duties involving the bacteriological analyses of frozen foods—The Director, Fruit and Vegetable Canning and Quick Freezing Research Association, The Research Station, Chipping Campden, Glos.

LECTURER (with a good honours degree in biology or botany and preferably experience on the mode of action of herbicides) IN BIOLOGY; and a LECTURER with a good honours degree in genetics, biology, zoology or microbiology) IN GENETICS—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1.

PRINCIPAL LECTURERS IN MECHANICAL ENGINEERING (two vacancies); and LECTURERS OR ASSISTANT LECTURERS IN MECHANICAL ENGINEERING (several vacancies)—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 21/G.

PRINCIPAL PHYSICIST at the Cardiff Radiotherapy Hospital—The Group Secretary, Whitchurch and Ely H.M.C., Whitchurch Hospital, Whitchurch, Cardiff.

RESEARCH ASSISTANT IN THE DEPARTMENT OF MUNICIPAL ENGINEERING, for work concerned with the performance of circular sedimentation tanks—The Registrar, Manchester College of Science and Technology, Sackville Street, Manchester 1.

RESEARCH ASSISTANT IN ZOOLOGY—The Registrar, University College of Wales, Aberystwyth.

RESEARCH ASSISTANT (with a good honours degree in physics, but candidates graduating this summer may apply) IN PHYSICS, for research in the field of radiation physics—Head, Department of Mathematics and Physics, The Polytechnic, 309 Regent Street, London, W.1.

TECHNICIAN, Grade II (with some microbiological experience) IN THE DEPARTMENT OF GENETICS, to assist with research in microbial and bacterial genetics—The Registrar, The University, Liverpool 3, quoting Ref. 365.

TEMPORARY LECTURER (medically or non-medically qualified, with a special interest in endocrinology) IN THERAPEUTICS IN THE DEPARTMENT OF PHARMACOLOGY AND THERAPEUTICS—The Secretary, University of St. Andrews, Queen's College, Dundee.

"THE SHAPE OF THINGS TO COME"

A BROADSHEET issued by Political and Economic Planning on January 1, 1951, *Prospects of a Decade*, sought to forecast some of the dominant trends of the nineteen-fifties. This document was used as the basis in preparing a provocative and wide-ranging broadsheet which has now been issued under the title *The Shape of the Sixties**. The new broadsheet discusses with sense and insight the possibility of a scientific approach to forecasting in the 'sixties, the world population explosion, changes in population structure and Britain's part in world affairs. Scientists especially will find the sections on the emergence of the technocracy and on discarding political junk stimulating as well as interesting. Taken with the statement on principles and aims of the Marlow Conference on social and industrial relations, issued last April and known as the Marlow Declaration, and with such books as Prof. K. Denbigh's *Science, Industry and Social Policy* (see p. 418 of this issue of *Nature*), it provides encouraging evidence of a new approach to industrial well as to social problems. It signposts the road along ich Britain must undoubtedly travel if she is to achieve ner economic growth, or the leadership in political and ial advances or in science and technology that is stil hin her capacity.

The broadsheet begins by insisting on an ecological proach to attempts at planning or forecasting whether the industrial or the economic or political field. It ticizes the neglect of the contribution which biology can ten make. In advocating the wider and more effective se of modern techniques, such as the computer and operational research, it points out that too often these have been dominated by the particular outlook and techniques of physicists and chemists and their engineering counterparts. Admittedly, the critical and detailed application of such methods would require much greater resources than are at present available as well as tackling numerous technical problems which are still unsolved. Nevertheless, the advances recently made in ecology point the way, and what is written in this broadsheet is strongly underlined by Prof. Denbigh's comments on the industrial order and the rise of what he terms "economicism"—the acceptance of economic criteria as the only ones of significance in society.

The broadsheet forecasts that as in the 'fifties the evermore rapidly expanding human race must content itself with crowding into the 3 per cent or so of the Earth's surface which is by nature reasonably habitable, the net effect of man's activities being still rather to diminish than to expand the total habitable area. The only technological advance possible during the 'sixties which would permit, even locally, a substantial increase in culturable acreage is considered to be a really low-cost and efficient means of mass-processing saline into fresh water. The United States has already invested heavily in the necessary research and development programme, and, apart from its bearing on the water situation in Britain, the mere possibility that by this means during the late 'sixties spectacular improvements may be effected in the situation of tropical and sub-tropical territories with potentially good soil and growing conditions and plants of salt or saline water—but at present limited by lack of fresh-water supplies—warrants much greater attention to desalination than it has yet received in Britain.

* *Planning*, 29, No. 471 (29 April, 1963) *The Shape of the Sixties*. Pp. 143–174. (London: Political and Economic Planning, 1963). 4*s*.

Although some civil engineering works involving major interference with geography may come close to practicability by the late 'sixties, such projects as damming the Behring Straits or the Straits of Gibraltar are regarded as belonging to a later period and so very unlikely to modify appreciably, during the 'sixties, the alarming impact of the world population explosion. The seriousness of the situation is brought out briefly but vividly in the broadsheet, which emphasizes the implications in terms of investment in industry, agriculture and services, in education, health and local government, and of threats to world peace of the existence from now on in India and China, for example, of multitudes of new paupers. This is especially so, at a time when economic progress and higher labour productivity imply high labour redundancies, especially in agriculture, new entrants to the labour force and some 5 million additional jobs per year cumulatively—in China the number of extra jobs required up to 1975 is put at seven times the present British population.

The broadsheet does not suggest that it is impossible to avert catastrophic breakdowns in meeting elementary needs and in preserving law and order in the countries thus affected. However, here it points out that the breakdown witnessed in the Congo may well be repeated elsewhere and that at best we must anticipate on a vastly greater scale problems of relief akin to those of the Depressed Areas of the 'twenties and 'thirties in Britain. It suggests that a distinction must even be drawn between two types of 'underdeveloped territories'. On one hand, there are those which are genuinely so named and are probably capable of achieving acceptable and worth-while rates of improvement in standards of living by means of loans and grants of manageable scale and character. On the other hand, there are the much larger problem areas where decades of international relief will be needed while efforts are made to bring the population into some kind of equilibrium with the means of supporting it with some human dignity, education and prospects in life. This may well imply greatly increased contributions from advanced countries through international agencies, restrictions on international movement, tighter international health regulations and a vast educational effort. The broadsheet also instances the need for greater resources for research into birth control, and foresees the possibility during the 'sixties of a mass supply of economically efficient and widely acceptable methods which by the 'seventies could effect a spectacular drop in the excess of births over deaths. The formidable problem of feeding the 500 million additional population expected must be tackled along well-tried lines, especially by the more general use of the best agricultural practices already developed in advanced countries.

It is perhaps significant that Prof. Denbigh, too, looks at this international background in considering the future shape of industry in Britain, and that both recognize that this huge army of uneducated, untrained, underfed, underprivileged recruits to humanity is being bred at the very moment when science and technology are rapidly undermining the need for and the status of the unskilled. The warning is to be read as plainly in the broadsheet and Prof. Denbigh's book as in Dr. S. Lilley's recent lecture on the scientific revolution and industrial processes (see *Nature*, 198, 1132; 1963). What stands out most emphatically is in fact the insufficiency of economic factors or

motives if the challenge of the 'sixties, let alone the 'seventies, is to be met. Prof. Denbigh goes so far as to suggest that the economic side may be expected to look after itself if we find the right spirit and guiding idea of how we wish to progress, and he suggests that our aim should be to build up a balanced culture in modern terms fostering interests and values complementary to the commercial and economic interests which have dominated the past two centuries.

In particular, Prof. Denbigh condemns the primitive character of industrialism as seen in the spendthrift use of natural resources, the chaotic and haphazard character of the industrial environment, and the general sense of temporariness and instability. He urges that an important function of industry in society should be that the employment it offers enables a man to put into his work much of himself, and the importance of this aspect of satisfaction is all the greater with the dilemma of unemployment that the inevitable advance of automation involves as Dr. Lilley so clearly shows. Both Dr. Lilley and Prof. Denbigh recognize the educational issue that is involved, and undoubtedly the leadership that is required to foster this new outlook and practice in industry depends a good deal on the ability of our universities and colleges of technology to supply men and women with the comprehensive outlook required and the capacity for leadership.

One great value of the Marlow Declaration is that it is calculated to stimulate further thought and enquiry into the nature of economics itself and particularly into this question of satisfaction in work and what the job contributes to the workman himself as well as to the consumer. The Marlow Declaration in fact places the employee back where he was in the social theory of the Middle Ages before, as Prof. Denbigh points out, the mutual obligations of worker and employer had been disrupted by the joint stock company which recognized only the obligations of shareholders. The purpose of industry as the fulfilment of human needs imposes on industry specific responsibilities to the employee, the shareholder, the consumer, the local community and to the nation. These are explicitly set forth in the Declaration which equally recognizes the need for self-discipline and a profound regard for human values and that the purposes of industry cannot be achieved without technical and economic efficiency, in which co-operation and internal discipline are important factors.

There is thus substantial support for Prof. Denbigh's contention that our real problem to-day is one of work, not one of leisure, and, in particular, of transforming the working-day into something that is satisfying in itself as well as productive. Moreover, the vital importance of a new outlook—and not only in industry—could scarcely be more emphatically illustrated than in Dr. Lilley's remark that automation is now beginning to reverse the trend, which has persisted for two hundred years, for the proportion of skilled workers in industry to decrease and the proportion of semi-skilled operators, and particularly of those doing repetitive work, to increase. Further, Political and Economic Planning envisages the early crumbling of the legendary of the cultured, liberal-minded, arts-educated administrator and business leader and of the recently unchallenged power of mass Trade Unions, particularly the industrial as distinct from the craft Unions.

The passing of these two dominant influences over modern Britain is seen as a consequence of the country's growing dependence on science and technology, and therefore on the professions and groups associated with them. This is contrasted with the declining capacity of arts-trained elements in the Establishment to obtain the necessary results and to maintain prestige and leadership in an increasingly technological civilization, as well as to the disenchantment of professional, clerical and skilled workers with often absurdly stupid use of industrial weapons by the unskilled workers Unions. Whether or not this forecast is sound—and it could be challenged—there are large problems of power and influence in Government involved here, but the broadsheet does not attempt to consider the relations between science and Government. Prof. Denbigh shows himself fully aware of the existence and nature of that problem, but is content to indicate that it needs study. Political and Economic Planning inclines to the view that scientists and technologists will play a larger part in the task of Government without suggesting precisely how. However, the broadsheet ventures to predict that the use by unskilled organized workers of the cruder types of industrial pressure for their own advantage is likely to be terminated by public resentment against past abuse and the existence of much larger numbers of available and reasonably fit retired persons, the competition of immigrants and of redundant workers from automated industries.

The broadsheet sees no reason in principle why during the 'sixties all parts of Britain should not share adequately in a growing prosperity. If this does not happen it will be due rather to failure of foresight, of local and national leadership and adaptability, and of competent planning rather than to any inherent difficulties and the disappearance of chronically different levels of regional unemployment would be a reliable index of health and successful adjustment in Britain during the 'sixties. Here, of course, education is an important factor and stressing particularly the need to foster adaptability. The broadsheet comments on the importance of a great and rapid development in postgraduate instruction and research, and in institutes to fill such alarming gaps as the lack of hybrid studies in technology and economics, or regional planning and technology. Research into the processes and problems of education itself is also likely to expand quickly and to influence the rate and direction of change, while university expansion itself may well determine many changes in social patterns.

The significance as well as the importance of this influence of a large increase in the graduate population emerges further when, in a subsequent section, the broadsheet discusses the discarding of obsolete political ideas and structure. The heart of the planning problem is now seen as to create the essential highly trained post-graduate cadre able to combine the necessary breadth of view with real professional expertise in asking and obtaining prompt answers to the right questions with the aid of mass data processing and sophisticated forecasting techniques. It is not, of course, suggested that these qualities are the necessary outcome of a university career, though, as both Prof. Denbigh and Dr. Lilley recognize, universities and colleges of technology, by modifying their courses, could go far to provide men and women with the qualities required. This is unquestionably of fundamental importance if we are to find planners who create harmony through diversity and opening new choices, rather than imposing uniformity and making the state the master instead of the servant of the nation.

What is required is that from mistrusting we learn to trust the planners and accordingly to evolve a sufficiently sophisticated type of politics to give them ample support,

from some of the best teaching centres in the U.S.—the Massachusetts Institute of Technology, Princeton, Swarthmore, Dartmouth and Bryn Mawr are examples only.

An error in the design of the mass spectrometer was noted: the slideways employ two vee-grooves, and impose too many constraints; one vee-groove and one flat should be used. Oddly, too, the drawings are full of redundant dimensions leaving the amateur mechanic too many checks to do and the professional a problem in deciding which to use as his reference planes. The shop equipment needed for each construction is listed (lathe, mill, air-gas torch, hand solder, etc.), and so are the materials and American sources of supply of some of them. One difficulty to be anticipated is that British standard fittings (screws, pipes, couplings) seldom match the American counterparts. It seems likely, however, that constructional kits for some of the apparatus are now available.

The letterpress occupies about the same number of pages as the drawings. In it, there are hints, warnings and advice about use, evidently prepared for the college lecturer (the art of making vacuum-tight soldered joints; field homogeneity and many tricks in the nuclear magnetic resonance apparatus).

The average educational level of the work seems to be about that of the college of advanced technology in Britain. Probably such colleges will benefit most of all from it, but other technical colleges and traditional universities will find it helpful too. Simply to open it is like a child's first visit to a Christmas toyshop; the brain seethes with phantom adventures and ideas.

After sober consideration, many of our teaching institutions are certain to benefit from this original but sensible work.

A. R. MEETHAM

BOOKS ON NUCLEAR GRAPHITE

Nuclear Graphite

OEEC Dragon Project Symposium, Bournemouth, November, 1959. Pp. 269. (Paris: Organization for European Economic Co-operation; European Nuclear Energy Agency, 1961.) n.p.

THE Organization for European Co-operation and Development (OECD) *Dragon* high-temperature gas-cooled, nuclear reactor project has now been in operation since 1959, and indeed the 25 MW experimental reactor is due to start up at the Atomic Energy Establishment, Winfrith, during next year. The project held its first symposium at Bournemouth in November 1959, and it was very appropriate that this first technical meeting should have been devoted entirely to graphite because, as the chief executive, C. A. Rennie, pointed out in his opening remarks, the whole concept of the *Dragon* reactor is based on the use of this material. Although the European Nuclear Energy Agency did not publish the proceedings of this conference until July 1961, the mass of information given on graphite manufacturing technology was, and still is, worthy of the attention of a much wider audience than the small one which met at Bournemouth in 1959. The publication in the United States of a more recent work with the same title, *Nuclear Graphite* (*Nature*, 128, 420, 1962) prompts a further glance at the earlier book from the European Organization.

The introductory paper by Dr. L. R. Shepherd outlined the design philosophy behind the *Dragon* reactor system, concluding that fuel element components would have to be developed to stand temperatures of 1,000–1,700° C, in an intense neutron field. Since graphite had been selected as the moderator, the main structural member and the fission product containment barrier in the core, the real purpose of the symposium was to assess what processes were currently available or capable of development for producing a suitable form of graphite.

It appeared that a fine-grained graphite of very low permeability and nuclear purity was required, and at the session on manufacture and properties of fine-grain graphite, papers from Morgan Crucible Co., Atomic Energy Research Establishment Chemical Engineering Division, Siemens-Planiawerke (Germany), Société Le Carbone Lorraine (France) and Société Pechiney (France) were presented to show the possibilities in this direction.

Impregnation techniques, as a means of lowering the permeability of fine-grained graphite, were also described, and finally, the various methods used in the laboratory for assessing the more important properties of the final graphite were described.

The title *Nuclear Graphite* for this collection of papers is somewhat misleading, since the book does not give any experience of the behaviour of graphite in-pile, and is solely devoted to considering the special form of graphite required for the *Dragon* high temperature gas-cooled reactor. Nevertheless, the information published on graphite-making is a valuable contribution to the literature, since so few papers appearing, prior to, or since this date have disclosed recipes for making special graphitic materials on a commercial scale.

F. ROBERTS

DESCRIPTIVE OCEANOGRAPHY

The Sea: Ideas and Observations on Progress in the Study of the Seas

Vol. 2: The Composition of Sea-Water, Comparative and Descriptive Oceanography. General Editor M. N. Hill. Pp. xv+554. (New York and London: Interscience Publishers, a division of John Wiley and Sons, 1963.) 150*s*.

THIS is the second of a series of three volumes surveying the present position in physical, chemical and geological oceanography. For reasons of space, marine biology has only been included where it has a direct bearing on these three fields of study.

Following the first volume on physical oceanography, Volume 2 contains a series of review articles on the chemistry and fertility of sea-water, the biological problems related to the various water masses—productivity, fishery dynamics and the distribution of organisms—and largely descriptive accounts of some of the principal current systems. Also included are some fascinating miscellanea such as the largely unexplained seasonal changes in sea-level, a topical discussion of bathyscaphs and deep submersibles, and the navigational and observational uses of the gyropendulum.

Some subjects which appear in this volume, chemical sampling instruments for example, are as old as oceanography itself, while others such as estuary dynamics or the use of neutral buoyant floats are of such recent development as to appear in a collected volume for the first time. It is most noticeable how in recent years a gradual dissolution of the traditional subject barriers has occurred. Chemistry and biology are now largely inseparable in oceanography, and both contribute to our knowledge of physical and dynamical processes. The geographical distribution of both organic and inorganic matter is closely related to the current systems, and a knowledge of these distributions provides information which would otherwise require extensive series of current measurements. The very extent of the oceans makes the task of gathering information most formidable, and in this context the present international programme of observations in the Indian Ocean will prove of great value. It is gratifying to read that even radioactive fall-out yields some useful information on oceanic mixing and the general circulation.

The experts contributing to this volume continue the extremely high standard set in Volume 1, both in comprehensiveness and in the stimulating presentation of their special topics. Not only oceanographers but also all

who are interested in the sea will find themselves sharing their enthusiasm.

One criticism to be levelled at this volume results from the neglect of certain important topics such as western boundary currents. The editors apparently hope to rectify these omissions in a possible fourth volume. The printing and editorial work are again excellent. J. N. Hunt

SILICATES

L'analyses des silicates

By I. A. Voinovitch, J. Debras-Guedon and J. Louvrier. Pp. 510. (Paris: Hermann, 1962). 48 NF.

THE experience of the authors of this book is derived from several recent years in control of analytical operations at the Centre National d'Etudes et de Recherches Céramiques, and silicates here include a wide range of industrial products and raw materials associated with the manufacture of ceramics and with the building industry. Now that the analyst may have at his disposal a variety of physical techniques to supplement or replace chemical methods of analysis, some guidance in the scope and application of these techniques is highly relevant, and it is appropriate that in Part 1, comprising the first four chapters, some physical methods of analysis are discussed at sufficient length to be of real value to the non-specialist. These are flame photometry, absorption spectrophotometry including atomic absorption, emission spectroscopy, and X-ray methods by direct emission and by fluorescence.

Part 2 is concerned with analytical techniques, and begins with a chapter on dry and wet methods of chemical attack appropriate to various classes of materials. This very comprehensive and useful section is followed by a series of schemes for the analysis of aluminous, silico-aluminous and siliceous materials, carbonates, enamels, zircon refractories, chrome refractories, slags, mortars, and soluble clay extracts. Individual spectrographic methods covering approximately the same range of items, occupy the next 52 pages, and there is a short section on some applications of flame photometry by the authors' special 'oxine' technique which is claimed to give increased sensitivity and a reduction of mutual interferences for a number of common elements in the oxy-acetylene flame.

The remaining 200 pages are devoted to chemical methods, varying in number for each of the 28 elements dealt with according to the importance and difficulty of determination of the element; thus aluminium is given twelve methods, gravimetric, volumetric and colorimetric, some of which are, however, variations on a few basic methods, while silicon is alloted five methods, manganese three, and molybdenum one. The layout allows such items as reagents, concentration ranges, interfering ions, and the preparation of standards to be clearly and concisely presented. 'Classical' methods are freely supplemented by colorimetric and compleximetric procedures. Silicon is, for example, determined gravimetrically following an alkaline fusion, by fixation either with hydrochloric acid in the presence of gelatine, or by evaporation with sulphuric acid; or volumetrically by precipitation as potassium fluosilicate with an acidimetric finish; or colorimetrically as silicomolybdic acid with or without reduction to molybdenum blue. Separations by extraction with organic solvents seem to be avoided even, for example, in the colorimetric determination of copper by diethyldithiocarbamate, the coloured compound being here measured in aqueous suspension stabilized by a gum solution. The colorimetric determination of iron by *o*-phenanthroline or dipyridyl is now generally preferred to the one given using sulphosalicylic acid, and no method for ferrous iron has been included. At least one colorimetric method for phosphate would be expected in addition to the two gravimetric methods described. The absence of an index may also be noted in criticism; but the arrangement of the book makes this omission only occasionally a source of inconvenience.

These criticisms on points of detail need not be assumed to detract seriously from the value of a book which contains such a large amount of useful material, clearly and systematically presented, and which is certain to become widely consulted in industrial and other laboratories where siliceous materials are analysed. G. A. Sergeant

THE MIND AT REST

Sleeping and Waking: Physiology and Psychology

By Ian Oswald. Pp. ix+232. (Amsterdam and New York: Elsevier Publishing Co., 1962.) 45*s*. net.

DESPITE the large proportion of human life which is spent asleep, our knowledge of the mechanism of that state or of the biological function which it serves remains unsatisfactory. There is a dearth of good books on the subject, and, as Dr. Oswald says in his preface, most students have relied for nearly 25 years on the book of Kleitman. This has been joined by one of the symposia of the Ciba Foundation, but there remained a need for an account of the work which has been done on sleep since the thirties. It must be said at once that Dr. Oswald's book fills this need, and that it will undoubtedly become an essential part of the equipment of anybody working in this area.

The book starts with a review of the various physiological mechanisms which have in recent years been shown to relate to sleep. These largely concern of course the reticular formation. The particular physiological changes occurring in human sleep are then outlined; and this leads into an account of the changes in the electroencephalogram found during sleep. Using these changes as an indicator of the presence of sleep, the book then proceeds to a discussion of the changes in reaction, memory, and so on which occur at the borders of sleep. A discussion of the physiology and psychology of directed attention and of imagery then leads into an account of some of the curious subjective experiences and hallucinations which may occur when falling asleep or awakening, and so to dreams and the physiological changes which are now known to accompany them. The remaining chapters provide brief discussion of other functions similar to sleep which may be assimilated to it, such as animal hypnosis, experimental neurosis, the occurrence of deaths from emotional shock, fatigue in skilled tasks, brainwashing, and so on. There is a brief mention of diurnal rhythm, a chapter on the effects which may follow deprivation of sleep, and an account of some clinical conditions connected with sleep.

Any attempt to cover this wide topic in a reasonably short space must of course have some biases and limitations. It might perhaps be fair to characterize those which actually appear by saying that the book is much stronger on sleeping than it is on waking. In part this is, of course, because the physiology of sleep has been better studied than has that of alertness during the waking state. Unfortunately, however, Dr. Oswald supplements the real physiology of sleep with some hypothetical suggestions about the role of imagery in human thinking and about the underlying physiological mechanisms which organize and control it, and these can only be described as highly controversial. In general, the thesis is that behaviour becomes increasingly organized as one passes further from sleep towards a high state of cerebral "vigilance"; no consideration whatever is given to the work of psychologists such as D. O. Hebb, K. W. Spence, or the later publications of D. E. Berlyne, who have tried to grapple with the difficulty that thought and behaviour may become inefficient under conditions widely different from those of sleep. Indeed, Dr. Oswald himself describes the hallucinations occurring on the verge of sleep

as similar to those of schizophrenia; and yet also notes elsewhere that amphetamine in large doses will produce the same symptoms. One is therefore somewhat suspicious of Dr. Oswald's repeated suggestion that an inefficiency in behaviour is an indication of incipient sleep.

An engaging feature of the book is the author's willingness to state bluntly his own views on matters which are in dispute. In some such cases he is, from my point of view, on the side of the angels: for example, in questioning the suggestion by Dement that deprivation of dreams rather than deprivation of sleep produces disturbances of behaviour. Another example is Dr. Oswald's opposition to the suggestion of Malmo and Surwillo that deprivation of sleep produces a state of increased arousal. Nevertheless, and no matter how much one agrees with Dr. Oswald, there are a few cases where one feels that the other side of the controversy might have had a little more representation.

In summary therefore, this is an excellent review of the phenomena of sleep and at least a stimulating introduction to those of returning consciousness. It is written with attack and confidence, and liberally illustrated with incidents and cases known to the author. While it has the defects of its good qualities, it is bound to command the field for years to come. D. E. BROADBENT

MYCOLOGY FROM AN UNUSUAL ANGLE

Fungal Genetics.

By Dr. J. R. S. Fincham and Dr. P. R. Day. (Botanical Monographs, Vol. 4.) Pp. x+300. (Oxford : Blackwell Scientific Publications, 1963.) 50*s*. net.

THE present appalling dichotomy in biology, and particularly in the way it is taught and investigated in Britain, comes to mind at once in reading this useful book. On one hand there is 'classical' biology, with its sub-divisions either as to groups of organisms—botany, zoology, microbiology—or as to form and function: comparative anatomy, comparative physiology, ecology, ethology and evolution. On the other hand, there are the recent approaches represented by genetics, molecular biology, cell biology and cellular biochemistry. These have produced in the past twenty-five years a revolution at least as illuminating and far-reaching as that of the nineteenth century linked to Darwin's name.

Some of the practitioners of classical biology ignore, fear, affect contempt for, or, at best, pay lip service to the new ideas and techniques instead of being glad to absorb them in their own daily way of thinking and working. So far the chasm can still be bridged, because the older practitioners of the new biology, by virtue of age and training, have their roots in classical biology: their aim is still that of looking at the same problems in a new light. But the coming generation of molecular biologists, biochemical geneticists and cell biologists may not have any roots at all. If the dichotomy is allowed to go on we shall have two kinds of biologists: those who label migratory birds and those who label ribonucleic acids, neither knowing of the other, and each considering himself as the 'true' biologist.

In this respect, the book under review has a very refreshing quality. Though the authors state that their own research work "has not been instigated primarily by an interest in fungi for their own sake", in fact, out of a total of eleven chapters, at least three—one, introductory, on the biology of those fungi on which genetic research has been substantial, one on sexual development and one on pathogenicity—do reveal such interest, which also appears sporadically throughout. In other words, this is a book in which the dichotomy is not apparent. Since it is a very readable and good account of fungal genetics, which is, after all, an aspect of the biology of fungi, every mycologist should read it and assimilate it. For the geneticist—microbial or macrobial—it will be an indispensable reference book. The authors have made a real and successful effort not to limit their account to their own research interests, important as they are. There could perhaps be a little more about yeasts, but the mixed nature of the literature in this field makes the task very difficult.

The genetics of fungi has contributed decisively to some of the basic problems of genetics: recombination, complementation and alternatives to sex. The parts of the book dealing with these problems make stimulating reading. In addition, the detailed treatment of tetrad analysis is a useful teaching tool. There is throughout the crop of misprints which has become a familiar feature of present printing standards. There are also here and there a few minor factual mistakes and wrong or omitted references: these are minor flaws. The authors can be congratulated on having filled a gap very well.

G. PONTECORVO

BETWEEN THE TIDE-MARKS

British Seaweeds

(The Kew Series). By Carola I. Dickinson. Pp. 232+12 plates. (London: Eyre and Spottiswoode, 1963.) 25*s*.

DURING the nineteenth century when scrap-books, often very beautiful in character, occupied the leisure hours of ladies of fashion, a number of popular books were written, illustrating and describing the commoner seaweeds of British coasts. With the passage of time and life's increased pace these books have ceased to be available and they have not hitherto been replaced. Large numbers of people spend holidays near the shore, but comparatively few of them are aware of the fascinating occupants, both plant and animal, of the area between the tide-marks; modern books, with rare notable exceptions, mostly biological, have not been designed to help them. It is particularly appropriate therefore that Miss Dickinson's book should have been published just now when a determined effort is being made by both national and local bodies to revive the general interest in natural history.

The book is of convenient size and is illustrated by twelve colour plates, mostly of outstanding merit. There are also 92 text figures which vary very much in quality, some, such as those illustrating the species of *Laminaria*, being very beautiful, though others are much less pleasing.

Following a short introduction, the author gives a short account of the structure of seaweeds, their reproduction and their life-cycles. Brief sections follow on environment, collecting and mounting specimens and on the uses of seaweeds. A key to genera precedes an account of some 150 of the commoner British species. The descriptions of the species are written in a semi-popular style so that they can be used by an amateur and a glossary helps to elucidate the terminology. The book is indexed and there is a brief bibliography.

The problem of writing for the layman on such an unfamiliar subject must be recognized, and the author has obviously striven to make the descriptions both lucid and interesting. It is a pity, nevertheless, that in the introduction, words like 'rhizome' and 'stolon' are used without qualification. One hopes that some amateurs will be fired with sufficient enthusiasm to become formal students, so it is a pity to teach them to use words that are only applicable strictly to higher plants. In the same section a statement occurs that "holdfast indicates the sole function of this organ". That is certainly not true, for it may also be an organ of perennation and regeneration in both brown and red algae. These, however, are small points, and the book as a whole is a welcome addition to a series which is making a great deal of valuable material available to British naturalists, in a most attractive form.

LILY NEWTON

Science, Industry and Social Policy

By Kenneth Denbigh. Pp. vii+103. (Edinburgh: Oliver and Boyd, Ltd., 1963.) 16*s*.

THIS brief social criticism of applied science and industry is a notable tract for the times in the true lineage of Patrick Geddes and Lewis Mumford. Written with a refreshing freedom from jargon and giving ample and well-chosen references for further reading, it is a most stimulating challenge to thought as to what new forms of social progress we can achieve in our modern industrial societies. In particular, it challenges the over-emphasis on the economic factor, contending that the overdue orientation of the industrial order needs to be achieved in a social much more than in a purely economic sense. Moreover, while Prof. Denbigh pleads cogently for the individual and the need to preserve freedom of choice and opportunity in his conception of planning he displays the imagination and vision which mark Geddes and Mumford at their best.

The seven chapters of this book in which, successively, Prof. Denbigh discusses trenchantly the short-comings and primitiveness of industrialism as it moves forward, as he believes, into a new phase, the rise of 'economicism', as he describes the practice of accepting economic factors as if they were the only criterion, the relations of consumers versus producers, in which he pleads that work should be so planned and organized as to provide satisfaction to the producer; the paradox of resources, in which our failures in planning industry, towns, transport, etc., are overwhelmingly pilloried, on transcending the machine, on the public conscience and private uncertainty, and on science and world conditions abroad in stimulating suggestions. Questions are raised, implicitly or explicitly, and in a context of realism and vision, which should set the reader searching for an answer. Here is no blue-print for a new social or industrial order but some very shrewd pointers to the way in which that order may be created. The scientist will find some questions about the control of research expenditure or the relations between the scientist and Government which are the more suggestive because they are so unexpectedly raised. The book is short but never superficial, well written and full of ideas, many of which have long since been ventilated but are now formulated with fresh meaning in the context of to-day's needs and potentialities. R. Brightman

Enzymes and Drug Action

Edited by Dr. J. L. Mongar and A. V. S. de Reuck. (Ciba Foundation Symposium, jointly with the Co-ordinating Committee for Symposia on Drug Action.) Pp. xv+556. (London: J. and A. Churchill, Ltd., 1962.) 65*s*. net.

THE scope of this symposium is not as wide as its title would suggest. On the enzymatic side, it includes a paper on carbonic anhydrase and some discussion of microsomal enzymes involved in drug metabolism, but it is weighted disproportionately towards acetyl choline esterase. The drugs considered are mainly those affecting muscular contraction or acting on the central nervous system; the action of some hormones is also discussed.

The symposium, which was held in March 1961, was in two parts. The first part was a large gathering at which nineteen formal papers were presented. A report of this meeting occupies the first 400 pages of the book. The papers are preponderantly pharmacological in outlook, variable in standard, and many are repetitions of work published elsewhere. The discussions in this part are scrappy and irritating to read; they contribute little of scientific value, though in places they show a lively atmosphere of controversy. The second part, reported in the last 120 pages of the book, is much more valuable. It records the informal discussions of a selected group of about thirty well-known physiologists, pharmacologists, biochemists and physical chemists on such debatable and elusive problems as active transport, the nature of receptor sites and the mechanism of insulin action. The meetings were in four sessions devoted to the general topics of enzymes, receptors, and interactions at sub-cellular and cellular levels. These discussions reveal starkly the lack of common ground between the participants in their basic assumptions and in their methods. A lack of agreement in the interpretation of their results is scarcely surprising, and the outcome of most of the arguments is inconclusive, but the conflict is fascinating and illuminating to the reader. This is a big, untidy book plentifully sprinkled with misprints. It is not a book to keep for reference, but parts of it should provide stimulating thoughts for anyone interested in the way in which drugs work. G. A. Snow

Annual Review of Nuclear Science

Vol. 12. Edited by Emilio Segre. Pp. 633. (Palo Alto, California: Annual Reviews, Inc., 1962.) 8.50 dollars.

ONCE again the editors of the *Annual Review of Nuclear Science* present a series of review articles by authorities in a wide range of specialist topics in nuclear physics. The technical articles cover the subjects of the preparation of thin films for sources and targets, semiconductor particle detectors and research reactors, and theoretical articles cover the subjects of compound statistical features in nuclear reactions, electron exchange reactions, dispersion relation methods in strong interactions, and nuclear astrophysics. In between these extremes are articles on inelastic electron scattering, polarization measurements on β- and γ-rays, and an article on the Mössbauer effect. With a more chemical bias are two articles on isotopic exchange reactions and free radicals in irradiated biological materials.

It would be a wide-ranging physicist indeed who found more than half these articles of more than passing interest, but all active physicists will find this volume a valuable work of reference. T. E. Cranshaw

A New Mesozoic Flora from Tico, Santa Cruz Province, Argentina

By S. Archangelsky. *Bulletin of the British Museum (Natural History): Geology*, 8, No. 2. Pp. 47, 12 plates. (London: British Museum (Natural History), 1963). 30*s*.

SELDOM now does a fossil flora prove almost entirely new, but this one from the Upper Mesozoic of the Argentine does. The present paper deals with Pteridosperm-like leaves and conifer shoots (with a few associated fructifications). They have well-preserved cuticles which are described in detail. The stomata in some are remarkably like those of *Cycas revoluta*, though the finely divided leaf looks like a fern. They are placed in five new genera, and, while the number of genera of such leaves is already inconveniently large, it is hard to see what else could have been done with leaves as odd as these. A little two-seeded fruit is associated with one of them; it is quite unlike anything produced by a cycad, but more like *Caytonia*.

Most of the conifers are new species of *Brachyphyllum;* one is of interest in being associated with *Araucaria*-like male cones. One of the most interesting species in the flora and the only one previously known is *Athrotaxis ungeri*, previously described by Halle on material with no cuticles but with female cones. The cuticle of this fossil now proves very close to that of *A. cupressoides*, which still survives in Tasmania; it is thus a gymnosperm of greatly reduced range.

We may hope that further collection and study will add considerably to knowledge of these plants, which may represent some entirely unfamiliar families.

Tom M. Harris

TECHNICAL DEVELOPMENTS IN THE ELECTRICITY SUPPLY INDUSTRY*

By Dr. HARRY TAYLOR
Director of the Electrical Research Association, Leatherhead

Generation

PROPERTIES of Steam. In the early days of electricity supply, when almost every town had its 'electric light works', the generation of steam as a preliminary to the generation of electricity was a simple matter: simple, but not at all economical. Boilers operated at low pressures and were often fired by hand; engines were of the reciprocating type, with belt-drive to the dynamos.

Steam engine builders were then dependent on very primitive steam tables. With the coming of the turbine, however, and large power stations which supplied not single towns but extensive areas, came the need for increase in steam pressure and temperature to improve turbine efficiency, also an urgent demand for fresh data; and about 1900 Prof. H. L. Callendar began his life-long investigation of the properties of steam which provided the data for the higher pressures and temperatures so essential to turbine designers.

The Electrical Research Association supported, almost from the date of its formation, the work of Prof. Callendar. His investigation of the properties of steam led the Association to arrange international co-operation through the International Steam Tables Conferences held during 1929, 1930 and 1934, in London, Berlin and New York, respectively, and the final result was the publication of the 1939 *Callendar Steam Tables* giving the properties of steam up to pressures of 3,200 lb./in.^{2} and temperatures of 1,000° F.

Prof. Callendar's son and Sir Alfred Egerton carried on these researches, supported by the Association, and the researches have in recent years been under the control of Prof. D. M. Newitt and Mr. S. Angus, who have extended the work up to 14,000 lb./in.^{2} at 1,100° F and to somewhat lower pressures at higher temperatures.

The Association has continued to play a full part in international collaboration, conferences having been held in Moscow and Munich and planned for New York. As a result, *British Steam Tables* will shortly be available up to a range of temperature and pressure well in advance of anything needed to-day. Having achieved this position, and having paid for most of the British research over a period of forty years, the Association feels that it has achieved something well worth while, and can now safely leave it to others to carry on in a range which is full of theoretical interest but little practical importance to-day.

Properties of Steel. The efficiency of power generation has improved over the years. In the 'twenties, anything above 20 per cent was a figure to be proud of; to-day, all modern stations exceed 30 per cent, and the highest efficiency recorded by the Central Electricity Generating Board during 1961–62 was 34·5 per cent. Many factors contribute to improved efficiency, such as increased unit size, increased combustion temperature, reduced flue gas temperature, better thermal insulation, regenerative feed heating, combustion air pre-heating and hydrogen cooling of the alternator, but none of these single features is so important as higher working temperatures and pressures of the steam. These set a limit to the efficiency theoretically obtainable. The story cannot be continued better than by reproducing the words of Dr. N. P. Allen of the National Physical Laboratory (*Co-operative Electrical Research*, 13, July 1961):

"But there is a limit to the temperatures and pressures that the materials of construction can withstand, and if too severely stressed at high temperatures, superheater tubes and steampipes will swell gradually, and perhaps burst, turbine rotors and blades will deform, to the detriment of the dimensional accuracy upon which the working of the turbine depends, and bolted joints will relax, and no longer be able to prevent the escape of steam.

"It has therefore been necessary to determine very accurately the maximum stresses that the materials of construction can sustain at each temperature, and this has proved to be complicated, since steels at high temperature undergo slow changes which generally reduce their strength. Electricity generating stations operate as a rule for upwards of twenty years, and to be sure that no difficulties will arise in this period, very prolonged tests of several years' duration have to be made. If, in the interests of increased thermal efficiency, steam temperatures and pressures are raised, new steels, stronger and more heat-resistant than the old, have to be developed, and these must be subjected to an extensive and tedious process of testing before their capabilities can be properly assessed.

"When, about forty years ago, it was first realised that the high temperature properties of steel would limit the efficiency of electricity generation, it was not uncommon for steam to be raised at 600 psi and 680° F (360° C). Today, steam conditions of 2,000 psi and 1050° F (565° C) are becoming commonplace. The value of the saving of fuel, due to improved efficiency is immense, amounting to many millions of pounds every year. But it is known that heat-resisting steels and other materials exist which make it possible to do even better. Efficiencies of over 40 per cent are in sight, and 45 per cent appears to be worth working for.

"The Electrical Research Association first came into this work in 1930. At that time there was great controversy about the methods to be employed in the testing of steel at high temperature, and still more controversy about the way in which the results should be used in design. The Electrical Research Association formed a committee, upon which steel makers and turbine makers and users were represented, and this committee sponsored the accurate investigation at the National Physical Laboratory of the high temperature behaviour of certain typical steels. The mechanical testing was done in the Engineering Division of the National Physical Laboratory and the associated changes of metallurgical structure were examined in the Metallurgy Division. Very satisfactory methods of testing were developed, and in due course a creep testing laboratory was built which contained upwards of forty high-accuracy creep-testing machines. This was at that time considered a very large and up-to-date equipment, upon which the equipment of several other laboratories was modelled. Mild steel was examined first, and then 0·5 per cent molybdenum steel, and a variety of other low alloy steels, in various forms.

"As knowledge of the properties of steels increased, and steam-raising temperatures rose, the number of special creep resisting alloys that it became desirable to examine also rose. The combined effect of these three influences was that the testing programme expanded to such an extent that the creep testing laboratory at the National Physical Laboratory was quite unable to cope with it. It

* Substance of the Fifteenth W. M. Thornton Lecture delivered on June 14 during the Convention of the Association Mining Electrical and Mechanical Engineers at Newcastle upon Tyne.

was therefore decided to build a new and larger creep testing laboratory at the Electrical Research Association, Leatherhead, which would be devoted principally to long time tests."

This laboratory, which is one of the finest in the country, solely devoted to work on the creep of steel, has no less than 600 test points. Of these, 50 are devoted to high precision creep testing such as is required for steel used for turbines, and the remainder are used for 'time-to-rupture' tests, which is the information chiefly needed for boilers, steam pipes and superheater tubes.

The Electricity Council's Annual Report for 1957–58 states that—"The consumption of coal at the power stations in England and Wales in the ten years since vesting day would have been some 41·4 million tons greater and would have cost some £147 m. more, if average thermal efficiency had remained at the 1947–48 level."

Through its work on the creep of steel, the Electrical Research Association claims credit for at least a small part of this saving.

Steam Pipe Welds. It has now become standard practice in modern power stations using steam at the higher temperatures to eliminate bolted pipe joints wherever possible by welding. This practice has introduced the need for intensive investigation of the service life to be expected from welded joints. In view of the absence of adequate service experience of welded pipe joints in the materials they proposed to use for the new high temperature stations, the Central Electricity Authority expressed a wish for some full-scale testing of pipe welds made on specimen pieces of finished steampipe. The Authority through its Eastern Division, made available to the Association a site at Brimsdown 'A' Power Station (where steam is used at a pressure of 1,900 lb./in.^{2} and 930° F) where such tests could be carried out in electric furnaces so that the temperature could be raised to 1,100° F in order to accelerate the tests.

Briefly, the purpose of the test at Brimsdown Power Station was to simulate so far as possible conditions to be met with in the projected high-pressure high-temperature plants, and under these conditions to test the behaviour of sample butt-welded steampipes supplied by various manufacturers both under continuous high temperature and under cyclic temperature variation to represent operation when plant is started up daily or after week-end stoppage.

It is hoped to have available after a period of testing, material from which information can be obtained as to the conditions of steam-pipe welds in actual service. The test may also be regarded as a useful warning of anything untoward happening in welds that are in service, however unlikely this may be.

The test gear consists of two bell-type air circulating metal tempering furnaces, each containing a group of five pressure vessels fed with a small supply of steam at approximately 1,900 lb./in.^{2} pressure, the extra heat to maintain the vessels at the required temperature being provided by electrical heating. This test rig has in recent years been taken over and completely operated by the Central Electricity Generating Board, which is the organization primarily interested in the results.

Condenser Research. In the steam-generating field other investigations have been undertaken, in co-operation with the Institute of Metals and with the British Non-Ferrous Metals Research Association, on the corrosion of condenser tubes, the Electrical Research Association contributing towards the expense. New alloys were tested, and investigations made on the effect of the presence of impurities both in the tubes and in the cooling water.

An investigation of heat transmission coefficients was also carried out in the University of Manchester for the Association, to furnish a sound theoretical basis and provide new data for condenser designers.

Steam Nozzles. In the early days of its interest in power generation, the Association supported research on the design of turbine steam nozzles. This research, which extended over a period of eight years, was conducted in the Manchester Corporation Electricity Department and made a substantial contribution to the improvement of turbine efficiency.

Miscellaneous Researches. The Association has been responsible for organizing, supporting or co-ordinating a wide range of investigations in the field of power generation. The principal ones have already been mentioned, but others relate to microscopic and mechanical tests of turbine blading material, aquatic growths in condenser systems, effect of biological action on corrosion of condenser tubes, vibration of power station pipework, joint tightness of pipe flanges, grindability of coal and dust sampling of power station flues.

In the field of steam power generation of electric energy the Association has issued no less than 152 reports to its members, and many of these have since been published.

Transmission Lines

Lightning and Surges. Thunderstorms are less frequent in Great Britain than in many countries where transmission and distribution of electricity are effected largely by means of overhead lines, but even in Britain lightning is the most frequent single cause of supply interruptions. Statistics show that there are about 5,000 such interruptions each year, but the situation is not as serious as this criterion might imply. On 11 kV systems, for example, supply can be restored merely by replacing fuses or reclosing circuit breakers in about 80 per cent of cases. In a further 5 per cent damage is only slight and supply can be restored immediately, repair being deferred until convenient; only in the remaining 15 per cent of cases is it necessary to repair damage before the supply can be restored.

Sufficient is known about lightning and its effects to render it possible to secure complete lightning protection in nearly all cases, but to do so for even the majority of lines would add considerably to the cost of electricity. An occasional interruption may be inconvenient, but a big increase in the cost of electricity would be more so. An attempt at complete protection would be justified only for the most important lines; but there are relatively inexpensive palliative measures which can be applied to most lines.

The Association has for a number of years received records of all interruptions to supply which occur in Britain, and an analysis of these will lead in due course to general guidance on the means of providing the appropriate degree of protection to a line consistent with its importance.

Research on surge phenomena was started by the Association in 1930. Until then knowledge of the subject had been gained principally by researches elsewhere, particularly in the United States, and it was important to ascertain the bearing of this on British conditions and methods, also to fill many gaps in the data available. A certain amount of experimental work was done, and in 1933 financial assistance from the Central Electricity Board made it possible to expand the programme considerably, with the collaboration of the National Physical Laboratory and of manufacturers possessing the requisite experience, and to extend research to actual working conditions in the field rather than confining it to the laboratory.

In the autumn of 1935, the Central Electricity Board placed at the disposal of the Association an eight-mile length of overhead line, designed to operate at 33,000 V, which had been erected but was not urgently required for service, and a little later two more lines, each normally operating at 132,000 V, one fifty miles and the other twenty miles in length. Tests on these lines provided

information on the behaviour of different types of surge and the efficacy of the several types of protective device.

As transmission voltages increase to 400 kV and above, a stage is reached when the insulation-levels required against external overvoltages caused by lightning may be equalled or even exceeded by those needed to withstand the so-called internal overvoltages, due to deliberate or involuntary switching operations. A great amount of statistical and experimental data is required to provide information for the design of high-voltage equipment and for a determination of the operational conditions under which the various types of overvoltage are liable to arise.

As the first stage of this work a fully automatic cathode-ray oscillograph was designed several years ago. This equipment, known as the 'E.R.A. Surge Recorder', is housed in a trailer for installation in a sub-station. Connexion is made to the high-voltage system by means of specially designed voltage dividers, utilizing tapped bushings on a transformer as the high-voltage arms, when these are available. The equipment consists essentially of a three-element high-speed oscillograph combined with a rotating drum camera and an electronic circuit which continuously monitors the system voltages. The function of the monitoring circuit is to initiate the beams of the cathode-ray tubes when the system voltage, on any one phase, is subject to a disturbance exceeding in severity a pre-determined level. Severity is judged broadly in terms of rate of rise of voltage.

Each record shows the three-phase voltages for the duration of the disturbance. The recording material is a strip of film one metre long carried on the rotating drum, one revolution corresponding to about three cycles at power frequency. After completion of a record by extinction of the cathode-ray beams, the camera lens is shifted to bring another similar strip of film into recording position in readiness for the next disturbance. The drum rotates continuously and the cathode-ray tubes remain continuously energized (except that the beams are normally extinguished) until three disturbances have been recorded. Recording then ceases but can be restored by exchanging the camera drum for another similar drum loaded with unexposed film, an operation not requiring any special skill. At the instant at which any record is taken an automatic camera photographs a clock face in order to establish the time of the event.

This recorder, which is unequalled anywhere in the world, has been in operation for several years, mostly on the British high-voltage system. A large amount of statistical information has been assembled and many of the results obtained in automatic operations or during specific staged test series have been reported. In addition, evidence has been collected on the wave shapes of different types of switching surge. This information provides a valuable contribution to present-day discussions on standardization of what may be regarded as a typical switching surge.

As already indicated, the importance of switching overvoltages and their effects increase with increasing transmission voltage. In the British Commonwealth, 500 kV and 700 kV systems are being actively discussed. In many of these cases long lines and comparatively small sub-stations will be involved, thus increasing the risk of the occurrence of much more dangerous switching overvoltages than those to be expected in a highly interconnected system with large sub-stations as in Britain. The Association hopes to assist in the solution of at least some of the many outstanding problems to which answers are urgently needed.

Transformers: Short-circuit Forces. It has long been recognized that if a transformer is to give satisfactory service it must be capable of withstanding an occasional short-circuit. Specifications usually stipulate that this requirement shall be met with full voltage maintained across the primary terminals.

Prior to 1940 there was no reason to suppose that all was not well. Transformer designers used accepted methods for calculating the stresses produced by short-circuit currents and designed accordingly.

The introduction of barrage balloons during the Second World War produced conditions which had never previously been encountered. These balloons sometimes broke loose, drifted across country and their cables short-circuited overhead lines. Some transformers failed to withstand these abnormal conditions and interest in short-circuit forces was re-awakened. It was recognized that mechanical failure could be a cumulative process. The greater the asymmetry of the windings, the greater are the forces imposed by a short-circuit. Insulating materials are not perfectly elastic, and compressive forces can effect a permanent reduction in thickness. Consequently one short-circuit can increase the forces imposed by its successor.

The problem was submitted to the Electrical Research Association and a comprehensive investigation was undertaken. This comprised two main parts: (1) investigation of the forces involved; (2) examination of the effects of these on typical insulating materials.

Many reports have been issued on the subject of forces in transformers, and to-day there is little that is not known about the subject. A mathematical investigation has indicated the possibility of a simplified digital computer programme for the calculation of axial magnetic forces and interest is now centring on the dynamic behaviour of the windings under axial short-circuit forces and the determination of the strength of windings to resist these forces.

That the problem is a very real one still is shown by the fact that short-circuit forces were the principal cause of failure on the multiple-unit electric train in the Scottish Region. The Ministry of Transport report in its conclusions reads as follows:

"The damage was caused principally by the frequent application of severe electromagnetic forces, sufficient gradually to distort the outer layers of the secondary windings. This led to the over-riding of turns, high inter-turn pressure, the scuffing of paper insulation and its eventual breakdown."

Transformer Oils. The Electrical Research Association is responsible for various kinds of co-operative research, and this is one where its staff exercises only a co-ordinating function. The contending parties—if such is the right term—are the users of switchgear and transformers on one hand and the suppliers of oil, on the other. As early as 1910 the two parties were talking about sludging of oil and means of avoiding it. The Insulating Oils Sub-Committee played a useful part in the early days, and the work was taken over by the Association on its formation.

Investigations have been made of sludging, acidity tests, electric strength tests, maintenance of oils in service, international standards, inhibitors, and many other aspects of the use of oil in electrical apparatus. All this work has largely been done by the oil supply industry, the laboratories of the electrical supply and manufacturing industry, and the universities. In the last case the Association has provided the money.

Unfortunately, it cannot be said, even to-day, that all the problems are solved, but there is very much less trouble with such oils to-day than there was when the inquiries first started. During this year there will be completed ten years of testing inhibited oils in transformers under practical use in the London area.

Transformers: Ventilation of Sub-stations. Prior to the investigation by the Association no satisfactory method, confirmed by tests, had been produced for determining the performance of the ventilating inlets and outlets of sub-stations. As a beginning of the Association's work, equations were derived theoretically, and were found by independent workers to give closer agreement with experiment than any earlier work. It was still considered,

however, that a comprehensive investigation was essential to cover the detailed effects of ventilator sizes, types and positions on air and transformer temperatures. A small sub-station housing a 100 kV amp 50 c/s transformer has been erected in the laboratory; removable panels in walls and roof allow ventilators of a wide range of sizes to be inserted in practically any position. Transformer, air, and wall surface temperatures are measured by an array of thermocouples. To minimize the effects of changes of laboratory temperature, two sets of lagged thermometers are used to give reference temperatures.

From the experimental results, expressions have been obtained to link the transformer temperature and losses with the ventilation parameters of the sub-station. The discharge coefficients of various types of ventilators are calculated from the air temperature measurements. Inlet ducts, outlet chimneys and fans in ventilators or on the transformer are among other aspects receiving attention.

Overhead Transmission Lines: Tower Footings. Clearly, maximum economy is achieved in the design of an overhead line tower if the strength of the tower in bending is equal to the strength of the foundations in resisting overturning. If the tower bends before it pulls out then it is too weak; conversely, if it pulls over without permanent deformation of the structure itself, then the foundations are too weak. Obviously with varying soil types, it is impossible always to balance one against the other, but experiments were required to determine whether the two modes of failure were approximately the same. These showed that in certain conditions the foundations failed with only half the load required to buckle the tower. If this is a fair generalization—and further experiments are necessary to find out whether it is or not—then the economy possible in tower construction costs over the whole country is very considerable. On the other hand, it could be said that because of inadequate knowledge, the factor of safety on the foundations was inadequate and that these failed when, in fact, neither foundations nor tower should fail.

Overhead Transmission Lines: Wood Poles and Wind Loading. The Association made a comprehensive investigation in the period 1920–30 on the materials and methods used for the construction of overhead lines.

This concerned mainly the strength of single and compound wooden poles. Six designs of compound pole were used—two being 'A' poles, one an 'H' pole, another a French design, another the Rutter pole and finally, one known as the Wedmore pole, after its inventor, the first director of the Electrical Research Association, Mr. E. B. Wedmore. This was a very scientifically designed pole since two separate poles were bolted together with thicker spacers in the middle length than at the ends. In this way the outer fibres of the double poles were pre-stressed in tension and the inner fibres in compression. Since wood is stronger in tension than compression, the pre-stressed pole can be shown to be stronger than a simple Rutter pole.

In concluding his paper to the Institute of Electrical Engineers on this pole research, the late Mr. W. B. Woodhouse said: "The Association's work has for the first time placed the design of compound poles on a sound basis, has condemned as unsound and uneconomical the types in common use, and has evolved new designs in which the materials are used to greatly increased advantage."

It seems remarkable that at this date it was still necessary to make wind-tunnel tests to find the pressure exerted on poles, stranded conductors and lattice towers, but such was in fact the case, and the Electrical Research Association arranged for this basic work done at the National Physical Laboratory. Of the three problems, that of greatest practical importance was the wind loading on stranded conductors, which were shown to react appreciably differently from smooth conductors.

In the discussion following his paper, Mr. Wedmore complained of the shortage of funds for research. He said " . . . we find nothing in it [the paper] which could not have been done ten years ago if the Association had then been given the money to spend which it has been given since. . . . It is obvious to everyone that the paper represents a very big present to the whole industry, showing a return of probably 100 to 1 on the expenditure." This was not the last time that Mr. Wedmore or his successors complained about the shortage of funds, or was able to point to great advantage accruing from research work.

Overhead Transmission Lines: Bond Strength of Reinforcements. This is a good example of a problem clearly defined and restricted in scope which was experimentally investigated and completely solved. So often problems are far from clear, and their elucidation only reveals more unknowns. 'The more one learns, the more there is to learn' is so often the case.

The problem was simple: was the bond-strength between the galvanized leg of a steel tower and the surrounding concrete adequate to prevent slipping without the use of bolts, cleats, or deformations, before the tower buckled? The answer was 'Yes', and the bolts, cleats and deformations have since been abandoned, with a small saving in time and cost for every erected tower.

It should be explained that when the concrete is broken away from a galvanized leg, it comes away quite easily and cleanly, so that there was ample reason to doubt the shear strength.

Overhead Transmission Lines: Strength and Vibration of Conductors. Extensive tests were made on hard drawn copper and aluminium wire and conductors, as a result of which the strength of conductors was expressed in terms of the strength of individual wires, the limit of proportionality and its variation with loading was determined, and new figures were given for the elastic moduli. The properties of composite conductors consisting of steel and aluminium wires were also determined, and the load sharing between steel and aluminium was ascertained, to the great advantage of overhead line designers.

Æolian vibration of wires is very well known, and many of us as children must have put an ear to a telegraph pole to hear the singing of the wires. The vibrations are caused when the frequency with which eddies are thrown off from opposite sides of the line corresponds with the natural frequency, or a multiple of the natural frequency, of the span.

With stranded conductors the continual vibration, which is generally associated with low wind speeds, gives rise to strand failure at or near the clamps. Between layers it is described as 'nicking', and between clamp and outer layer it is called 'hammering'. The former appears to be a case of fretting corrosion such as commonly arises when the parts are firmly clamped together but where microscopic movements can still take place.

The explanation for the vibration, with examples of mitigative measures, was given by Whitehead and Morgan in an early report of the Association, and experiments and further inquiries were reported in 1940 by Double and Tuck, also of the Association. The importance of nicking and hammering was clearly shown in the latter work, and these authors examined various types of damper and a German vibration-free conductor. They showed that lines most prone to the trouble were those having a small ratio of weight per unit length to diameter, for example, steel-cored aluminium conductors and hollow copper conductors—but that vibration does not always cause failure. They advocated the use of dampers and showed that trouble was reduced with lowering of tension and reinforcing the conductor at clamps.

In recent years the matter has come to the fore again with the object of finding whether the working tension of low power rural lines could be increased to allow a corresponding increase of span length. It was anticipated that fatigue failure at points of support might arise with the increased tension, but all the evidence goes to show that the principal failures were those of the binding, not the

conductor, and that the advantages of increased tension did not justify the additional risk of failure.

Overhead Transmission Lines: Current Ratings. The current which a conductor can carry depends on the permissible temperature rise and the rate at which heat produced is dissipated. In the case of overhead lines the dissipation is by radiation and convection—the former being affected by the absorption due to solar radiation, and the latter being affected by the wind velocity. Other complicating factors are the stranding, and the emissivity of the conductor surface, which depends very much on its age and the weather conditions in the locality.

In order that the maximum safe current for any overhead line in any given condition could be ascertained, it was necessary to make experiments to determine the coefficients of convection heat loss in still air and in wind of various speeds, the emissivity of the conductor surface, and the effect of stranding on the electrical resistance of the conductor (and hence the heating) and on the loss of heat by convection. All these factors were unknown when the Electrical Research Association started its researches before the War; but by the time the work was completed and reported in 1949, it could be said that data were available which made it possible to determine the safe current for any practicable conductor in any reasonable condition of use. This work still stands to-day, and, in fact, is now probably more greatly valued than ever before, as it is becoming increasingly important, for economic reasons, to avoid over-design.

Interesting features which came out of these investigations were that: (1) Smooth conductors cool by convection better than do stranded ones. (2) A wind as low as 1 m.p.h. (which is the minimum sustained value generally encountered in Great Britain) increases the permissible current by as much as 50 per cent for a large power line and by even greater amounts for small lines. (3) Aged conductors can carry appreciably more current than new ones for a given temperature rise.

Circuit Breaking. Circuit breakers are the key pieces of apparatus protecting electrical systems, and their contacts form part of the electrical circuits which they are designed to break when they separate. The insulating gap formed between these separating contacts is the final barrier in the protection of the generating plant and equipment and, if the initial arc between them fails to clear, great damage, amounting at times to disaster, may result.

The first director of the Electrical Research Association was a switchgear designer, so it is scarcely surprising that its first experimental work was in this field. In those days a heavy circuit breaker was one capable of breaking 150–250 MV amp. To-day, the largest breakers will cope with about one hundred times this amount of energy, and the system generally used, namely, the air-blast extinction, is the one invented by Wedmore and Whitney within five years of starting research on circuit breaking.

To-day the breaking capacity of circuit breakers has become so large that it is impossible to test them at full capacity and there is great interest in what is called 'synthetic testing'. This is a system in which the current and voltage at break are supplied from different sources and the energy used is small, although the circuit breaker is submitted to what it is hoped are identical conditions to those occurring in a full power test. The Electrical Research Association produced the circuit which makes this kind of test possible, and extensive investigations are in hand to ascertain on relatively small circuit breakers whether in fact their behaviour under power breaks is identical with their behaviour under synthetic tests. If it is, and the position is thoroughly verified, then it will be possible to accept synthetic tests as a means of measuring the rupturing capacity of the largest breakers—an achievement which would be of very great value to the power supply industry and to the manufacturers.

Network Analysis. The complexity of a problem does not have to be very great before pencil-and-paper calculation becomes formidable. In some of these cases the results will best be obtained with the aid of a digital computer, but often the necessary calculations may be greatly assisted by using a model. Such a technique is well established for investigating the behaviour of ships in tanks or aircraft in wind tunnels.

It is even easier to construct a model to represent the behaviour of an electrical network, since the electrical quantities can be modelled independently of the physical size of the system. Furthermore, in most circuits the quantities may be considered to be linear, that is, doubling the voltage doubles the current.

Electrical network models—or 'network analysers'—are like other models in that their various parts represent parts of the original system to a definite scale and measurements on the model can be referred to the actual system values by means of a known scale factor.

When the Association was considering building a network analyser, various aspects of its use had to be borne in mind. It was recognized that internal research would not occupy the analyser full time and that it would be available for use by individual members, especially the supply industry and consultants.

As is well known the Association has, over a long period, been actively concerned with investigating the flow of harmonics in power systems and rates-of-rise of restriking voltage. The analyser had, therefore, to be well suited to these investigations. This was achieved by designing an analyser for operation not at a single frequency only but over a frequency-range of 100 : 1.

The Electrical Research Association analyser can be used to study, for normal operating conditions, the flow of active and reactive power, busbar voltages, the effect of changing transformer taps, and the effect of varying the source of power. These are what are called steady-state conditions, but the analyser can equally well be used for transient conditions such as increasing the peak power which a circuit breaker may have to clear under fault conditions and the effect of the location of the fault.

There are many network analysers in the country, but few have the accuracy and versatility of that at the Electrical Research Association, which was entirely designed and made by the staff and is now in constant use.

Fire Fighting. The dangers of fire need no emphasis, even in ordinary conditions; but when a fire occurs in or near an electrical installation, very special risks become prominent which need expert knowledge and an entirely revised technique if they are to be quickly and effectively countered.

One of the most serious situations, where electrical plant is concerned, occurs when fire threatens a power station, or a large sub-station; inflammable insulating materials, such as oil in quantity for switchgear and transformers, rubber and other substances are here part of the normal equipment. Even a comparatively small fire then becomes an imminent danger to the continuity of supply. Experience of such fires indicated that they were difficult to deal with, not only on account of the presence of inflammable materials, but also because fire officers feared risk to the lives of their men owing to the live electrical gear. Instances are on record where fires which could have been extinguished at an early stage have become dangerous through delays due to this quite natural hesitation. The Association therefore put in hand a thorough investigation of methods suitable for combating fires in electrical installations, with particular reference to oil fires.

The knowledge thus gained proved most valuable. Permanent records were obtained by the use of colour cinematography of the behaviour of fires and of fire extinguishing. After analysis, the results of the whole series were placed at the disposal of the electrical industry, the fire plant industry, the London Fire Brigade, and the Fire Officers' Committee, and through this enterprise a complete set of recommendations was drawn up which

now serve as a basis of instruction on the handling of electrical fires.

High-Voltage d.c. Transmission. This subject was considered so important in Germany that a high-voltage d.c. Berlin-Elbe trial line project was started during the Second World War (in 1941) and persisted in despite heavy air-raid damage to the Berlin terminal station.

The system was ready for tests when the Russians occupied their sector, dismantled the plant, and sent it east without allowing any tests to be made.

The late Dr. F. Busemann, who joined the staff of the Electrical Research Association in 1947, was an outstanding expert on the subject and, while with the Association, wrote twenty-three technical reports, filed some half-dozen patents, and made check tests, using the Association's model transmission system.

Section B: Transmission of Power at High Voltages, first met in May 1949, and prepared a detailed high-voltage d.c. transmission trial scheme giving particulars of equipment required, costs involved, and a time schedule for construction. The cost was £1½ million spread over seven years.

At a meeting of Section B in the summer of 1951, this scheme was referred to in a lengthy report to Council, who set up a panel to consider the matters raised. In 1955 the panel recommended that the future need for high-voltage d.c. transmission in Great Britain, and especially abroad, called for immediate inception of a programme of development and trial, and that manufacturers should be urged at high level to initiate valve development for a rating of 50–150 kV 250 amp, and assurance should be sought that one or more manufacturers were prepared to commence such development forthwith. In the meantime, Section B should proceed with its investigations to provide all the information possible.

These recommendations came to nothing; they were in advance of their time. Industry, both manufacturing and supply, was too concerned with nuclear power development to devote staff or money to high-voltage d.c., but within a very few years, the success of the Swedish Gotland scheme directed attention to the possibility of a d.c. cross-Channel link and this, as is well known, was eventually carried out, the necessary valve research having been done in Sweden. Once again Electrical Research Association had pointed the way; others had followed.

Distribution

Cables. One of the Association's first tasks was to find a more scientific basis for cable loading. The co-operative nature of the Association's structure enabled the manufacturers on one hand to supply information on the maximum permissible temperature at which the cables could operate, the supply authorities to provide the means for carrying out field tests, and the staff of the Association to compute the corresponding ratings. The report on the first investigation furnished for the first time reliable information on the heating of buried cables in relation to cable design, properties of the soil and atmospheric conditions.

Research on cables has continued from that day till this, and a summary of the Association's achievements is given here. Most of the easier and more rewarding jobs have now been done; but investigations in hand at present are of very great importance, though undoubtedly difficult. Examples are the determination of the effect of the grain size distribution of backfill sand on the movement of moisture away from a loaded cable, and the assessment of cable deterioration and the reduction of life arising from overloading.

Summary of Achievements. (*a*) Considerable economies in the use of cables already installed and in expenditure on new cables have resulted from investigations of cable ratings. This would have been brought to the stage at which continuous ratings for practically any type of cable and mode of installation are available or can readily be computed. The Electrical Research Association is the recognized standardizing body in Britain in this connexion.

(*b*) Similarly, cyclic and intermittent ratings are available or can be calculated by methods laid down by the Association for any load conditions specified.

(*c*) Short-circuit effects have been investigated and appropriate ratings are available for many types of cable.

(*d*) Recommendations have been made regarding the design and layout of joints and terminations for ducted cable runs so that failures in such runs, which have in the past resulted from movement of the cable, may be avoided.

(*e*) Methods of laying and bonding have been recommended which will avoid interference with communication systems, damage to cable sheaths by corrosion and hazards arising from excessive sheath voltages.

(*f*) Methods of test have been developed for the measurement of dielectric loss, impulse withstand and quality of insulation in cables and of thermal properties of soils.

(*g*) Considerable knowledge has been gained of the behaviour of soil under conditions of temperature gradient existing in the neighbourhood of buried cables, and the conditions are known in which the loading of a cable is such that the thermal resistance gradually increases to a very high value due to drying out.

Overhead Distribution Lines. In 1946 the Electrical Research Association issued a review of the work which it had done in the previous twenty-six years on overhead lines. This work, much of which applied to distribution lines, was covered by 44 reports dealing with properties of conductors, conductor clamps, insulators, wind pressure on lines and supports, shock and fire risk with wood poles, tower and pole foundations, concrete poles and line design.

Of all this work none was more important than that which culminated in the production of British Standards 1320: "High-Voltage Overhead Lines on Wood Poles for Lines up to and including 11 kV." This applies to both three-phase and single-phase distribution lines where the normal voltage to earth does not exceed 6·6 kV. The design is specified in detail and is based on an original design evolved by the Association. The specification describes the types and sizes of conductors, minimum height, length of span, details of supports, cross arms and insulators, earthing and loading. Conductor sags and tensions, and wind loading tables are also given.

In 1956 Mr. H. W. Grimmitt wrote of this work in *Co-operative Electrical Research*: "It is obvious that there is a substantial saving in money when overhead lines are erected according to B.S. 1320. . . . Last year about 3,490 miles of overhead lines were erected in England and Wales, to B.S. 1320. Of these, 3,118 miles were of 0·025 sq. in. copper or copper equivalent and 372 miles of 0·05 sq. in. This shows a saving of £423,400 . . . the above figures do not include the lines in Scotland or Northern Ireland. It would therefore not be unreasonable to suggest that at the present rate of construction, the E.R.A. has been the means of saving the Supply Industry about £500,000 a year."

Earthing and Safety. When the Electrical Research Association started to look into the subject of earthing in 1930, virtually nothing scientific was known about it by British electrical engineers. Practice was largely based on experience with lightning conductor earthing. The only earth electrode known was an iron casting set in coke and, whatever its shape, it was called an 'earthplate'. There was no knowledge as to how its resistance could be calculated, and instruments for measuring its resistance had only just appeared. No one measured soil resistivity; chemicals were never used to reduce the resistance; nothing was known about current loading capacity; cattle sometimes got shocks near earth electrodes but no systematic investigations had been made to account for the phenomenon; people got shocks in domestic installations but if an earthplate was provided the reason was regarded as a mystery. The whole situation was

thoroughly unsatisfactory and ripe for investigation, and since the supply industry, the contractors and the public were all involved, it was an appropriate subject for co-operative research.

Steady investigation through the 'thirties solved most of the problems and put the subject of protection by earthing on a sound basis, but it also revealed that satisfactory protection by earthing was not always economically feasible. Alternative methods were examined and practice in other countries studied. As a result, protective multiple earthing was introduced in Great Britain and found entirely satisfactory in areas of high soil resistivity. At first, as a precautionary measure, the conditions of application were somewhat onerous but, on the advice of the Association, these were later relaxed by the Ministry of Fuel and Power, and the system has since been more widely used with complete success.

Utilization

Space Heating. Most of the information so far given relates to improved methods of supplying electricity; but the Association has also made substantial contributions to what might be called the commercial or consumers' side of the industry, and one of the most important deals with the problem of floor heating.

One of the drawbacks of floor heating is that it cannot be turned off if the day should turn unexpectedly warm. The only solution for overheating in such circumstances is to open the windows. If, however, the heat extraction could be controlled, this would add greatly to the merits of off-peak underfloor heating, and research on means for doing this is now in progress. Also, investigations are being made to find out whether or not it is possible to control the heat input overnight (by controlling the time of switching on) to match the conditions forecast for the following day by the Meteorological Office.

There is no doubt that, with the continually rising standard of living, there is increasing use of central heating, and considerable research is still necessary if the electrical industry is to secure a good share of the potential business. Moreover, unless the energy is supplied "off-peak", such a load could well be an embarrassment rather than a blessing. Another move to prevent this is an investigation of chemical methods of thermal storage.

Rural Load Building. The Rural Electrification Department was formed by the Council of the Electrical Research Association in 1937 to encourage the extension of electricity supplies in rural areas by investigating methods by which the use of electricity in agriculture and horticulture could be increased with advantage to both consumer and supplier. The achievements of the supply industry since that time in fulfilling its rural electrification expansion programme have been greatly facilitated by the subsequent work of this Department.

During the twenty-five years of its existence, the Department has built up a valuable combination of experience, facilities, and contacts, enabling it to carry out research in the various aspects of the use of electricity in agriculture and horticulture. Since its inception the Department has produced 48 reports, dealing principally with the following subjects: soil heating, hay and grain drying, electrically driven farm machinery, soil sterilization, greenhouse lighting and heating for tomato and flower cultivation, effect of heat and light on poultry raising and egg laying.

This work has had a significant influence on the use of electricity on farms and in nurseries.

Integrating Meters. As a means of extending the life of the footstep-type bearing used in most electricity meters, extensive research has been carried out over a number of years by Mr. G. F. Shotter and Dr. G. F. Tagg which has led to a considerable knowledge of the phenomena associated with such bearings. Prior to this research very little was known of the many factors governing the performance of bearings of this type, but it is now possible, from the accumulated data obtained from this work, to design bearings with some certainty as to the performance that can be obtained. This knowledge has already been applied in practice and has led to a considerable saving of money to the supply undertakings in so far as the period of 'servicing' of meters has been extended. Whereas periods of the order of seven years were common some 15–20 years ago, the period can now be extended to twenty years when the principles laid down in the various reports of the Electrical Research Association are applied.

Radio Interference. From the earliest days of broadcasting, the Association has been involved in the problem of preventing radio interference. The power supply industry is affected in two ways: first, the low-voltage distribution systems are often the carriers of the interfering voltages, and second, at transmission voltage interference is created by corona discharge on lines and insulators, which is particularly noticeable during rain, fog, or snow.

The chief part which the Electrical Research Association has played has been to develop apparatus and methods for measuring the degree of interference, and to collaborate in arranging international standards of measurement. It has also been responsible for remarkable work on screening of radio waves so as to confine them to, or restrict them from, a given region. The application of this particular work made it possible to save about £10,000 in the type of screening used for the converter station for the cross-Channel power link.

Inductive Interference. When power and communication circuits run parallel to one another, currents in the former induce voltages in the latter which interfere with the satisfactory operation of telephone lines. From information collected by the Electrical Research Association, with the assistance of the Post Office, two main problems emerged: the danger of excessive induction in telephone circuits due to short circuits on power systems, and interference caused by unbalanced harmonic currents in power installations during normal operation. As a result of co-operation between the Post Office and the power authorities under guidance of the Association, and with the aid of the technical resources of the Association, these problems were analysed and finally overcome.

The work of the Electrical Research Association in this field has culminated in the production of a book which is a classic on the subject (H. R. J. Klewe, *Interference between Power Systems and Telecommunication Lines* (Edward Arnold, 1958)).

Load Research. To conceive electrical research as concerned only with the strength, electrical qualities, and suitability of materials to their purpose would be a mistake; there are many problems of direct interest to supply undertakings coming under what may be termed the human or personal aspect. After all, such undertakings serve a community, and a community is composed of individuals. What is their reaction to the electrical service offered? To what extent and in what manner do domestic consumers use electric cookers, water-heaters and other appliances; and in industrial areas is any special type of apparatus providing an exceptional load which requires special consideration?

The answers to these and other allied questions mean a great deal to the supply engineer; from them he can gather information which will enable him to determine the capacity of distribution plant, to estimate the cost of supply and, in brief, to plan his supply efficiently.

A section of the Association was formed during the Second World War to investigate such problems. Its activities fell under two general headings: "Load Research", and "Cost Research". Under the first, the characteristics of the various kinds and classes of loads on supply systems were investigated. The domestic field, owing to its potentialities, received particular attention, and extensive load records were obtained in a number of places; in addition, already existing material was

collected and analysed. In particular, tests were conducted in the systems of two undertakings with a view to deriving collective load curves of large groups of water-heaters.

Research into cost of electricity supply was conducted with the object of applying the scientific method to a field which, while of vital importance to the progress of electrification, had hitherto lacked systematic scientific treatment. As a basis for such treatment, a scientifically arranged system of cost classification was devised, with a view to being developed into a standard for the whole supply industry. A further step was the development of an improved method for allocating to classes of consumers the fixed portion of the cost of supply.

The work of this Section proved so successful that, by arrangement, it was taken over entirely by the Electricity Council.

Conclusion

The Electrical Research Association has many functions: it serves the manufacturers and users of electrical apparatus, the electricity supply industry and the general public. Its contribution to the supply industry has been selected for special attention here because it is a field in which its contribution is diminishing with the changing situation, and it seemed worthwhile to place on record the very significant part which the Association has played, particularly in the early days.

The nationalization of the electricity supply industry and its great increase in research activity has reduced its dependence on co-operative research at the Electrical Research Association. There is still, however, work to be done; the Association still makes a worthwhile contribution, and by adapting itself to the new situation, hopes to continue so to do for many years to come.

A MAGNETIZED ARTIFICIAL METEORITE

By Prof. CHARLES M. CARMICHAEL
Department of Geophysics, University of Western Ontario, London, Canada

On October 21, 1962, an object was found embedded in sod-covered ground which sloped at about 20° to the west, in Moore Township of Lambton County, Ontario, Canada, at about 42° 50′ latitude, 82° 17′ longitude. The sod was bulged up on the down-slope side, but the direction of entry appeared to be vertical. The broken sod was very fresh showing it had been disturbed since the last rain, which fell a week previously. In February 1963 I went to the site, cleared away the ice and snow and fitted the object into the hole to obtain a precise orientation relative to the Earth's magnetic field at the point of impact. Fig. 1 is a photograph of the object on the ground beside the impact hole, which is partly filled with water. The bottom of the hole is about 1 ft. below the mean surface.

The object weighs 15 kg and consists of two blocks of dark grey to black porous ceramic material. The blocks are fused together and are badly distorted by expansion on one side, but appear to have been originally rectangular with dimensions roughly 10 cm × 15 cm × 30 cm. The blocks were originally covered by a brick-red coating a few mm thick on the side and up to 1 cm thick at the corners, but this coating has come off about one-third of the total area. Polished section analysis shows the material to be an impure glass containing small grains of magnetite, ilmenite, hæmatite, pyrite and pyrrhotite. X-ray analysis of the undistorted part shows quartz, but in the expanded portions there is also the mineral cordierite. Heating experiments and the presence of cordierite indicate the expanded portion has been heated to a temperature of 1,000° C.

Eight cores 1¼ in. in diameter were drilled with a diamond core drill from the top and sides so as to include both undistorted and expanded material. From these, 15 separate specimens were cut for measurement in an astatic magnetometer. The directions of the remanent magnetization of the specimens are shown on a Schmidt plot in Fig. 2. This shows the whole block to be consistently magnetized throughout. The average direction of magnetization has a declination of 84° relative to magnetic north at the impact site and an inclination of 13° above the horizontal. A.C. demagnetization and field cooling experiments show the natural remanence of the expanded portion to be a thermoremanence produced by cooling from above the curie temperature in a field of slightly less than 0·5 œrsteds. The magnetization of the undistorted portion is also a thermoremanence produced in the same field below a temperature of 400° C.

A comparison of the impact of the object with that of the Dresden meteorite which fell in the same area in 1939, indicates an impact velocity consistent with free fall from above the dense atmosphere. Since the object is obviously man-made it can be best described as an artificial meteorite.

The properties of the artificial meteorite suggest that it is a part of the thermal shield of a satellite vehicle. The time of fall makes it probable that it came from 1962 *NU*1 or 1962 *B* β1 which decayed on October 17, 1962, and October 14, 1962, respectively. Of these the former, which is *Cosmos* 3 launched by the U.S.S.R. on April 24, 1962, seems most probable because of the date of its decay and the 49° inclination of its orbit. Another possible source could be one of the satellites in the National Aeronautics and Space Administration listing of June 25, 1963, which had not previously been announced.

From the physical distortion and the magnetic and thermal properties a probable sequence of events can be deduced. This portion of the thermal shield must have separated from the vehicle while in orbit or during the early stages of its re-entry. Since one side only shows evidence of being heated, the object achieved a stable orientation in the Earth's gravitational field. Friction

Fig. 1. Photograph of artificial meteorite beside the impact hole, which is partly filled with water. The holes are those left by the core drill used to get specimens for magnetic measurements; these holes are 2 in. in diameter

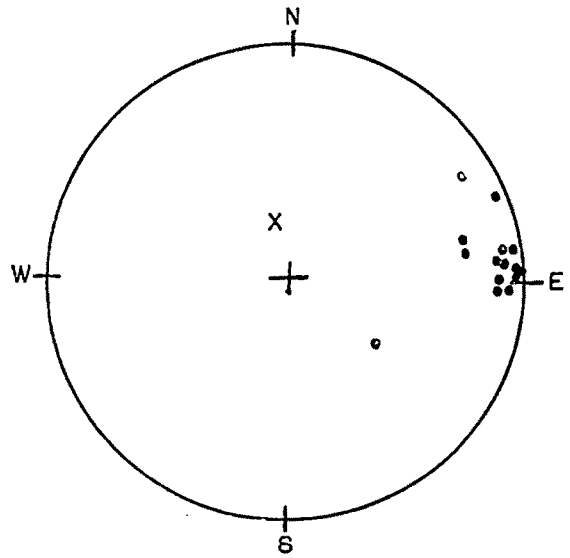

Fig. 2. Schmidt plot of the directions of the remanent magnetization of specimens cut from the artificial meteorite
O, Below horizontal; ●, above horizontal; ×, direction of Earth's magnetic field at the impact site

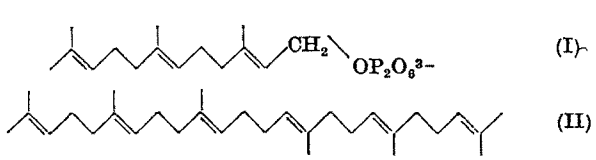
with the upper part of the atmosphere heated the forward portion at a rate balanced by conduction to maintain a surface temperature of 1,000°–1,200° C for a period of several hours. In the denser atmosphere the velocity would decrease more rapidly, an air cap would form and the temperature would fall. As the temperature fell below the curie temperature of the magnetic minerals they would receive their thermoremanence. Since the object was near the northerly limit of its orbit it would be travelling in a nearly west-to-east path so that the Earth's magnetic field would have an almost constant direction during cooling to produce a consistent magnetization. Near the end of its path the horizontal velocity would decrease rapidly, and it would go into a near-vertical free fall at a terminal velocity similar to that of meteorites. In this part of the flight the object would probably rotate slowly until it hit the Earth.

Whether one agrees with this sequence of events or not, these are several facts which are important for interpreting the magnetization of meteorites. An object has been heated in the atmosphere to a temperature of 1,000° C for a distance of 20 cm from its surface. It has since received a consistent thermoremanent magnetization which is not due to the Earth's field at the site of impact.

It would be most valuable if more information about the artificial meteorite could be obtained from the agency that launched it. A detailed report has been sent through Dr. D. C. Rose as chairman of COSPAR, to the Governments of the U.S.S.R. and the United States. This report will be published elsewhere.

MILSTEAD LABORATORY OF CHEMICAL ENZYMOLOGY, 'SHELL' RESEARCH, LTD.

By HUGH HARVEY



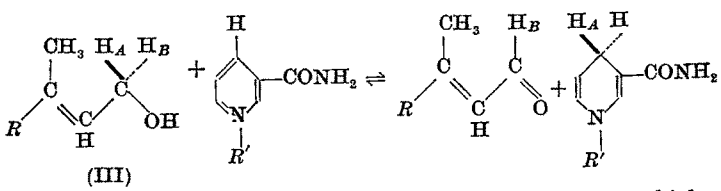
FOR the past thirty years or more the petroleum chemical industry has been supplying farmers with agricultural chemicals. These fall into two classes: fertilizers based on ammonia, and substances used for protecting plants, animals or man against harmful organisms. The second class includes insecticides, soil fumigants, fungicides, viricides, and weed-killers. Petroleum oils were originally used as insecticides in their own right; but the introduction during the Second World War of chlorinated hydrocarbons like DDT and BHC led to the use of chemicals from petroleum as raw materials for making synthetic pesticides. To-day the petroleum chemical companies manufacture and market not only chlorinated hydrocarbons but also organophosphorus and other compounds as well.

This relatively new field of endeavour has led to large-scale research programmes to find and test new chemicals, and to investigate the biochemical properties of the compounds under development. Serving the Royal Dutch/Shell Group of Companies are five laboratories concerned with various phases of research on agricultural chemicals. Two of these, Shell Development Company's Agricultural Research Division at Modesto in California and Woodstock Agricultural Research Centre at Sittingbourne, Kent, are concerned with many aspects of agricultural chemical research, all of which are directed towards increased efficiency in the production of food. In Germany, Shell Grundlagenforschung Gesellschaft at Schloss Birlinghoven works, *inter alia*, on the development of new synthetic routes and new compounds for biological screening at Woodstock and Modesto. Compounds emerging with promise from the screening process, which includes rigorous toxicological examination in the Tunstall Laboratory at Sittingbourne (*Nature*, 196, 809; 1962), are then synthesized on a larger scale to provide material for field trials and to explore manufacturing procedures.

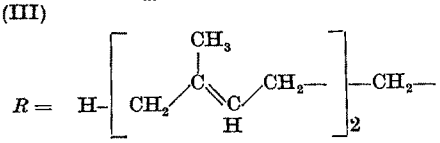
This research effort has recently been supplemented by the new Milstead Laboratory of Chemical Enzymology, also at Sittingbourne, which came into operation in April this year. This Laboratory is under the joint direction of Dr. J. W. Cornforth and Dr. G. J. Popják, both of whom, before taking over the new laboratory, were with the Medical Research Council. Both are Fellows of the Royal Society. As a team, they are best known for their joint work on the biosynthesis of cholesterol.

Their scientific collaboration goes back to 1948 when Dr. Cornforth was working with Sir Robert Robinson (past-president of the Royal Society) on the total synthesis of cholesterol. At that time Dr. Popják was pioneering the use of isotopes to investigate biosynthesis, and he suggested to Dr. Cornforth that it might be profitable to degrade cholesterol synthesized by liver from isotopically labelled precursors.

The degradation of cholesterol, biosynthesized from either $^{14}CH_3.COOH$ or from $CH_3.^{14}COOH$, was duly carried out, and the origin of every carbon atom in the ring structure from either the methyl or carboxyl carbon of acetate established. This and other work, notably by Bloch and Lynen, has made the overall course of sterol biosynthesis better understood than any other biochemical process of comparable complexity. Some of the enzymatic reactions which advance the synthesis step by step are of unusual interest, and elaborate experiments were required to throw light on their mechanism. For example, farnesyl pyrophosphate (I) gives rise to squalene (II),



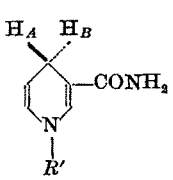
(I)



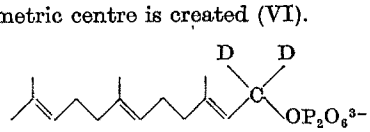
(II)

two molecules of precursor giving one of product in an apparently symmetrical manner. On detailed examination it turned out that the condensation of two molecules of farnesyl pyrophosphate to squalene was not a symmetrical process: one hydrogen atom attached to C-1 of one of the two farnesyl pyrophosphate molecules was lost in the reaction and was replaced by another supplied by reduced nicotinamide-adenine dinucleotide phosphate (NADPH). These experiments required chemical synthesis of isotopically labelled intermediates, biosynthesis by enzyme preparations, chemical degradation of enzymatic products on a micro-scale, crystallization of products in capillary tubes, and their final examination in a mass-spectrometer[1,2].

More recently, Cornforth, Popják *et al.* have shown that the synthesis of squalene from farnesyl pyrophosphate was an asymmetric process in the stereo-chemical sense: the hydrogen atom which is lost from (I) is that marked H_B in (III) and is epimeric with the hydrogen atom (H_A) removed by liver alcohol dehydrogenase from farnesol in the reaction:

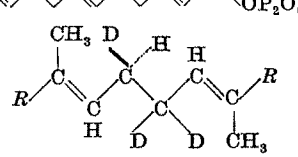


(III)



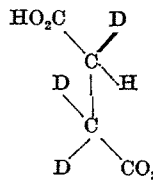
and R' = the remainder of the molecule of NADP or NADPH.

The external hydrogen atom replacing that removed from farnesyl pyrophosphate occupies also a sterically defined position in NADPH: H_B in formula (IV)[3,4]. Furthermore the insertion of hydrogen atom H_B from NADPH into squalene is likewise stereospecific; its absolute configuration was assigned recently. Thus, in squalene synthesized from 1-D_2-farnesyl pyrophosphate (V) with unlabelled NADPH:



(IV)

an asymmetric centre is created (VI).



(V)

(VI)

It was shown that the succinic acid, derived by chemical degradation, from the four central carbon atoms of (VI) contained three atoms of deuterium, was optically active and had the absolute configuration *S* shown in formula (VII)[5].

(VII)

These examples serve to demonstrate the value of combining chemical and biological approach to one end, the understanding of the mechanism of enzyme action.

The work of Shell's new laboratory will be concerned mainly with similar investigations of enzymes; but research on topics of shorter-range interest will also be undertaken. The object of the basic research will be to contribute towards a complete understanding of the workings of the living cell, a goal which no longer seems impossible to achieve in view of recent advances. For example, the realization that enzymatic reactions do in general observe the ordinary laws of chemical reactivity *in vitro* opens the way for fruitful investigations in which organic chemistry and biology are blended. It is for this reason that chemists and biologists have been recruited in equal numbers to the staff of Milstead Laboratory.

The shorter-range projects will lie mainly, but not exclusively, in the application of biological chemistry to the development of pesticides and herbicides. It is known that the action of the newer agricultural chemicals, like that of the older arsenic and mercury compounds, is due to their inhibition of enzymes. By examining and observing the part played by particular enzymes in cell metabolism, and the mechanism of their inhibition, it is hoped to make easier the design of agricultural chemicals lethal to selected species and innocuous to other forms of animal life. There is also the possibility that research along these lines may ultimately point the way to biological control of pests.

The staff of the laboratory will initially number thirty, of whom 14 are graduates in physical or biological sciences. In addition to the permanent staff, a limited number of visiting workers from other establishments will be welcomed, and there will be opportunities for post-graduates to work in the laboratories for periods up to three years. Equipment covers a wide range of modern chemical and biochemical techniques, and includes a mass spectrometer, a nuclear magnetic resonance spectrometer, and facilities for radioactive tracer work.

OBITUARIES

Prof. G. R. Goldsbrough, C.B.E., F.R.S.

Prof. George Ridsdale Goldsbrough, who died on May 26, 1963, at the age of eighty-two, had a long and distinguished association with King's College (formerly Armstrong College), Newcastle upon Tyne, in the University of Durham. He was a student at Armstrong College, and after graduating he held for fourteen years the post of senior mathematics master at Jarrow-on-Tyne County School. During this period he published papers in the *Proceedings of the London Mathematical Society* on the effect on ocean tides of variations in the depth of the sea and of coastal barriers. His interest in research led to his appointment to a lectureship in mathematics at Armstrong College in 1919, and he was very soon made

reader in dynamical astronomy and then, in 1928, professor of mathematics, which post he held until his retirement in 1948. He became head of the Department when Prof. T. H. Havelock (now Sir Thomas Havelock) retired, and as Sub-Rector of King's College during 1942–47, he played a most valuable part in seeing the College through difficult war-time years and those of the post-war expansion which was taking place. He was awarded the C.B.E. in 1948 for his work as chairman of the Durham University Joint Recruiting Board.

Although the dynamical theory of tides was his first and continuing interest in mathematical research and his papers on this subject appeared until 1954, mostly in the *Proceedings of the Royal Society*, the work that created most interest at the time was his theory of Saturn's rings. A theory of this unique ring system had been given by J. Clerk Maxwell in 1856, who concluded that it was composed of meteorites moving in circular orbits round the planet. The divisions in the ring system had to be accounted for, and the suggestion had been made that they were due to zones of instability around the planet set up by the satellites. In a fundamental paper in the *Philosophical Transactions of the Royal Society* (1922), which was followed by two papers in the *Proceedings*, Prof. Goldsbrough examined the influence of the satellites of Saturn on its ring system, on the basis of Maxwell's theory, and he was able to account for divisions in certain zones which were in good agreement with the salient observed features. For this work he was elected Fellow of the Royal Society in 1929. He returned to the subject again in 1941, when by a different method of solving the intricate perturbation problem, he clarified some points of criticism of his earlier work, and in 1951 he showed that, under conditions satisfied by the Saturnian rings, a pair of rings forms a stable system.

Prof. Goldsbrough had a clear, straightforward approach to any problem in hand, which, combined with his absolute integrity, led to his being much sought after as a counsellor in University affairs. He had an interest in all aspects of astronomy, and on many occasions gave lectures at meetings of the Newcastle upon Tyne Astronomical Society of which he was president during 1944–61. His wife died a few years ago, and he is survived by three daughters.

C. GILBERT

Prof. W. H. Lewis

WILLIAM HENRY LEWIS, who died on May 25 at the age of ninety-four, was educated at University College, Aberystwyth, and Jesus College, Oxford. After seven years (1894–1901) as science master at Exeter School, he joined the staff of the embryonic University College, Exeter, where he held the chair of chemistry from 1901 until 1935; he was vice-principal of the College from 1925 until 1935.

In the first few years of his tenure of the chair at Exeter, Lewis carried out research in organic chemistry and published a number of papers in collaboration with the late Dr. F. D. Chattaway, then at St. Bartholomew's Hospital Medical School. However, he soon found himself fully occupied with the affairs of the struggling young college and during the last thirty years of his occupancy of the chair devoted himself entirely to promoting the interests of the College and of his Department. During the First World War, Lewis, together with his colleagues, the late Prof. W. J. Harte and Prof. A. E. Morgan, was instrumental in the setting up of a Committee for the Furtherance of University Education in the South-west; there is no doubt that it was Lewis's devoted work as a secretary of this Committee which sowed the first seeds of growth which led, in due course, to the foundation, by Royal Charter in 1955, of the University of Exeter. Between the two World Wars much hard work was needed to get the University College fully accepted and once again Lewis was a leading member of a small group of devoted men, without whose efforts nothing lasting could have been achieved. The University College signalized its appreciation of his services by making Lewis professor emeritus on his retirement and the University by conferring on him, in 1957, the honorary degree of LL.D., a distinction which he greatly prized.

With all this, Lewis in no way neglected his Department. Starting from almost nothing, he built up a strong and active department of chemistry, with a striking record of academic successes in the external degree examination of the University of London and a sound reputation for research, which Lewis fostered by attracting good men to his staff and seeing to it that they had the facilities they needed for their work. He was responsible for the planning of new chemical laboratories, in the Washington Singer Building, opened in 1931; it would surely have pleased him to know that his old Department has now outgrown accommodation which must have seemed to many to be over-generous at the time.

Although so much involved in College affairs, Lewis found time to serve on the Council of the Royal Institute of Chemistry (1924–27) and on the External Council of the University of London (1930–35).

Lewis has rightly been called one of the founding fathers of the University of Exeter; as such he has an assured and honoured place in the history of English universities.

H. N. RYDON

Dr. G. Arnold, O.B.E.

WITH the death on August 9, 1962, of George Arnold, not only has the scientific world lost a great scientist but also we, in Africa, are deprived of a figure of outstanding merit, a redoubtable character.

Born in Hong Kong eighty-one years ago, his early education was undertaken, consecutively, in Devon, at Waldkirch in the Black Forest and at a senior school at Compiégne in France. He made full use of this early, varied education and, with his remarkably retentive memory, retained his knowledge of these languages throughout his days. After a spell of clerical work in London he commenced his scientific career at the Royal College of Science, and followed this with an appointment in the Department of Cytology and Cancer Research at the University of Liverpool.

In 1911, at the age of thirty, he was appointed to the curatorship of the ten-year-old Rhodesian Museum in Bulawayo, which eventually expanded, through his leadership, to become the National Museum of Southern Rhodesia and, largely through his investigations, an institute of international repute. Director of the Museum until 1947, he was for many years the only zoologist (in the wide sense) on the staff. Always outstandingly neat, a rare gift for a museum specialist, he was adept at casting reptiles and fish, adding all the intricate finishing touches himself.

Apart from building up vertebrate and insect collections his primary scientific interest was in the Aculeate Hymenoptera. Probably his earliest publication was a joint paper with J. E. S. Moore, director of cancer research. This was "On the Existence of Permanent Forms among the Chromosomes of the First Maiotic Division in Certain Animals", published in the *Proceedings of the Royal Society* (1905). This was followed by papers on chromosomes in *Hydrophilus*, on ovigenesis and on digestion in *Planaria*, on blood, epithelia and chondriosomes, the last of these cytological articles in 1912. Then, in 1912, Arnold read a paper to the Rhodesia Scientific Association on the "Foods of Ants" and afterwards his published works were mainly devoted to Hymenoptera. His first major entomological work was "A Monograph of the Formicidae of South Africa", published in the *Annals of the South African Museum* (1914–26). This was followed by "The Sphecidae of the Ethiopian Region" (1922–31) and "The Pompilidae of the Ethiopian Region" (1932–37) in the

Annals of the Transvaal Museum. A fourth book, *The Sphecidae of Madagascar*, was printed as a special memoir (No. 1) by the National Museum of Southern Rhodesia (1944). The last major work was entitled "Sphecidae and Pompilidae collected by Mr. K. M. Guichard in West Africa and Ethiopia", published as a bulletin by the British Museum (Natural History) (2, No. 3; 1951). Apart from these monographs many papers, chiefly on Hymenoptera, flowed from his pen; papers on the Formicidae and Methocidae of Africa south of the Zambezi, on the genera of African Apidae (1947), on the Mutillidae of Rhodesia and on the Sphecidae and Pompilidae of the Ethiopian Region; and a chapter on insects in the *Victoria Falls Handbook* (1952). The Hymenoptera papers continued after his retirement in 1947 and, in fact, right to the end of his days. He was the proud possessor of the honorary fellowship of the Royal Entomological Society of London, and he was elected president of the Rhodesia Scientific Association for the period 1917–19 and vice-president for several other terms of office.

Of small physical stature Arnold invariably made his presence felt. His alert brain was a formidable weapon in debate or argument, and his ready sense of humour earned him many an admirer even among those who had felt the biting lash of his criticism. He was severely dogmatic and a strong critic in his outlook on scientific workers in his own and other fields, particularly in economic entomology. I first came up against this aspect of his character about twenty years ago. Letters on official matters frequently contained some caustic comment directed at red tape or inefficiency. In his own systematic work he aspired to that point of view of taxonomy described as 'lumping'. To those who had only a passing acquaintance his acid comments sometimes caused resentment. But he always gave what he considered an honest opinion and on better acquaintance these traits were accepted as a matter of course, merely one of the characteristics of his active mind.

On any expedition, even into the roughest and wildest places, Arnold must have been almost unique for Africa in turning out immaculately dressed. This outfit would usually be a well-pressed tropical suit complete with waistcoat, tie, watch-chain and trilby. It did not matter what savage tribe or animals might be in the vicinity. In earlier days he was said to have worn spats, rather than leggings, against the attack of snakes, but in later years he evidently decided that long trousers were either adequate protection or at least more comfortable.

Arnold had enjoyed a last brief expedition not long before his death. He had completed his last paper, and I was able to show him the proofs of this—which he signed—on the night he died. Elliot Pinhey

NEWS and VIEWS

Director of the National Chemical Laboratory, Teddington : Prof. J. W. Mitchell, F.R.S.

Prof. John Wesley Mitchell, at present professor of physics in the University of Virginia, is to return to the United Kingdom following his appointment as director of the National Chemical Laboratory, Teddington. He succeeds Dr. J. S. Anderson, who has been appointed to the chair of inorganic chemistry in the University of Oxford (see *Nature*, 198, 135; 1963). The appointment takes effect from October 1. Prof. Mitchell was born and educated in New Zealand and is a graduate of the University of Canterbury. From 1935 until 1938 he was at Trinity College, Oxford, where he obtained his D.Phil. While at Oxford he worked with Sir Cyril Hinshelwood on a number of problems in chemical kinetics. During the Second World War he was with the Research Department of the Royal Arsenal, Woolwich, and later with the Ministry of Supply, where he developed high-speed photographic methods of studying the fragmentation of shells and the interaction of armour-piercing projectiles with targets. Prof. Mitchell was appointed lecturer in experimental physics in the University of Bristol in 1945, and reader in 1948. While at Bristol his main interests were in the surface properties of thin films of metals and in the nature and formation of the photographic latent image. Since 1959 he has been professor of physics at the University of Virginia, where he has built up a research group for work on the physical and chemical properties of single crystals of metals and other inorganic materials. His personal interests are, at present, principally in the study of the properties of the surfaces of single crystals of metals, in the synthesis of new inorganic materials and in the production of inorganic crystals of the highest possible chemical purity and physical perfection and the study of their properties. Prof. Mitchell was elected a Fellow of the Royal Society in 1956.

Chemistry at University College, London : Prof. A. Maccoll

Dr. Allan Maccoll, who was recently appointed by the University of London to a chair of chemistry tenable at University College as from October 1, 1963, arrived in England from the University of Sydney in 1945 to work on the mechanism of gas-phase reactions in Sir Christopher Ingold's Department at University College. As this work developed, it became apparent that there was a striking analogy between unimolecular gas-phase dehydrohalogenation and the reaction of substitution and elimination of the corresponding compounds occurring in a polar solvent. Further investigations led to the idea that there is a class of unimolecular gas phase reactions the mechanism of which is best interpreted as proceeding through a polarized ion pair transition state, and which is essentially heterolytic in character. These ideas received confirmation recently when rearrangements of the Wagner–Meerwein type, characteristic of carbonium ion mechanisms in a polar solvent, were reported for the gas-phase.

The recent installation of a high-resolution mass spectrometer in the Department of Chemistry at University College will greatly extend the scope of Dr. Maccoll's kinetic work, by making possible investigations of the energetics of carbonium-ion formation, and the effects of isotopic substitution on reaction rates. In addition, he hopes to tackle, by mass-spectrometry, problems of the structure of molecules of intermediate molecular weight. While Dr. Maccoll was at the University of Sydney he was awarded a 'blue' for swimming and was elected president of the Science Association, Chemical Society and the Sports Union. He has acted for many years as assistant tutor and adviser to chemistry students at University College, and during 1954–59 he served on the Council of the Chemical Society of London. Dr. Maccoll has long shown a special interest in the developing universities in the overseas territories which participated in the Special Relationship scheme of the University of London. He has from time to time visited them as London examiner in chemistry.

Electrical Engineering at Birmingham : Prof. H. A. Prime

Mr. H. A. Prime has been appointed to a new chair of electrical engineering in the University of Birmingham. The new chair is additional to those already held by Prof. D. G. Tucker (head of the Department) and Prof. J. T. Allanson. Its object is to enable much greater emphasis

to be placed on long-term research for industrial application. Mr. Prime's background is suited to this objective, as he is at present manager of the Application and Control Division of the Brush Electrical Engineering Co., Ltd., at Loughborough, having been during 1955–58 chief electronic engineer in the same firm. Mr. Prime, who is forty-two, was educated at the North Manchester Grammar School and the University of Manchester, from which he obtained an honours degree in physics in 1942 and later an M.Sc. He spent the years from 1942–46 in the Admiralty Signal and Radar Establishment, where he worked on radar and made a particular contribution to the work on displays. During 1946–50 he was a lecturer in electronics at the University of Liverpool and during 1950–55 was a senior lecturer in electronic engineering in the University of Adelaide, South Australia. During these years of academic work he did research in various fields of electronics including instrumentation, microwave measurements and ionized gases. In his eight years at the Brush Co., Mr. Prime has been responsible for some notable design and development work in control engineering. Perhaps the most spectacular has been his design of the control gear for both the Jodrell Bank radio telescope and the huge aerial installed at Goonhilly Down in connexion with satellite communication. But of more direct value to industry, no doubt, has been his work on the control of electrical machines. It is expected that Mr. Prime's appointment as the new professor at Birmingham will enable the Electrical Engineering Department eventually to make as big a contribution to industrial research as it is already making in various fields of communication and electronic engineering.

Controller of Aircraft, Ministry of Aviation : M. B. Morgan, C.B.

Mr. M. B. Morgan has been appointed to be the controller of aircraft, Ministry of Aviation, in succession to Sir George Gardner, who retired from the public service on April 29. Mr. Morgan was born in 1912 and educated at Rutlish School, Merton, and St. Catharine's College, Cambridge. He entered the Scientific Civil Service in 1935 at the Royal Aircraft Establishment and remained there until 1959. At the Royal Aircraft Establishment he was concerned, during 1935–39, with flight test work including aircrew tests, drag measurements, turbulence performance, stability and handling. During 1939–45 he was in charge of a group in the Aero Flight Section, dealing with handling stability and control, accident investigation liaison with firms, etc. From 1946 until 1948 he was superintendent (stability and control) and head of the Aero Flight Section concerned with all aspects of flight test work from helicopters to high-speed testing. In 1948 he was appointed head of Guided Weapons Department, and in 1959 became deputy director. In 1959, Mr. Morgan was appointed Scientific Adviser, Air Ministry, a post which he filled until 1960 when he was appointed Deputy Controller of Aircraft (Research and Development) in the Ministry of Aviation.

Royal Ontario Museum: Dr. W. E. Swinton

Dr. William E. Swinton has been appointed director of the Royal Ontario Museum (University of Toronto). Dr. Swinton, head of the Life Sciences Division of the Museum since 1961, succeeds Dr. T. A. Heinrich, who resigned last year. An internationally known authority on dinosaurs, Dr. Swinton, who is sixty-two, is the author of sixteen books and more than two hundred scientific papers and reports. During 1925–61, he was on the staff of the British Museum (Natural History), rising to principal scientific officer in charge of fossil amphibians, reptiles and birds. He was also training officer for non-curatorial staff and, for a time, chairman of the scientific staff association. Dr. Swinton was educated in Scotland at Trinity College, Clenalmond, and the University of Glasgow. In 1932 he was elected a Fellow of the Royal Society of Edinburgh. He was president of the Museums Association (Great Britain) during 1958–60.

Earthquake in Jugoslavia

On July 26, 1963, at approximately 5.18 a.m. local time, an earthquake of intensity about 9 on the Mercalli Scale (maximum 10) occurred with epicentre near latitude 42° 1′ N., longitude 21° 26′ E., near the centre of the town of Skoplje (Uskub) near the northern borders of Macedonia, in Jugoslavia. This follows smaller tremors in southern France a week earlier, and between then and July 26 in central Italy (Terni, 46 miles north-east of Rome). There was a slight earth tremor in Skoplje on February 22, 1963.

About half the buildings in the centre of Skoplje are reported to have been destroyed, including the Makedonija Hotel, the Jugoslav Army Club, the City Hall, the National Bank and a Teachers Training College. The Post Office was badly damaged and the telephone lines cut. The ancient fortress and the railway station were partly damaged, but the central hospital was not badly affected. Sewer and water pipes were cracked, electricity supplies cut, and fires were started because embers were thrown out of the grates. The death-roll is tentatively estimated at 1,000 from a population of some 215,000. In Gnjilane, 40 miles north of Skoplje along the Morava Valley, 24 houses were damaged, and the tremors were felt 100 miles away from the epicentre. After-shocks are continuing. The ruins of the ancient town of Scuppi, near by, are considered to have been caused by an earthquake in the year A.D. 518. Skoplje is approximately along the median line of a wide belt of epicentres which stretches from Mid-Atlantic, through southern Spain, Italy, Albania, Jugoslavia, Greece, Bulgaria and Turkey to Georgia, Azerbaijan and the Himalayas. An earthquake with epicentre west of Skoplje (42° N., 21° E.) occurred on 1942, August 27d. 06h. 14m. 11s. G.M.T., which is nearer to Tetovo than to Skoplje. It had magnitude 5·6 ± 0·3 on the Richter logarithmic (instrumental) scale. Further news from the locality, from Belgrade and from seismological observatories throughout the world is awaited.

Electric Power in Scotland

In a statement in the House of Commons on July 10, the Secretary of State for Scotland, Mr. M. Noble, said that the Government had given very careful consideration to the findings of the Mackenzie Committee, including its central recommendation that the functions of the two electricity boards in Scotland should be transferred to a single authority. In making this recommendation, the Committee's purpose, which must also be the Government's, was to ensure that the whole operation of generating, transmitting and distributing electricity in Scotland was carried out on the most economic basis possible, and that judgments on questions arising, such as the erection of new generating stations, were not influenced by narrow financial considerations. It was clear, however, that the proposal was unwelcome to a wide range of interests, and Mr. Noble did not think that it had yet been established that the continued existence of the two boards was incompatible with the most economic provision of electricity. He intended to see what could be done by close consultation and co-operation between the two boards, and, in the expectation that their purpose could be achieved by this means, the Government had decided not to proceed at the present time with the legislation that would be necessary to implement this recommendation of the Committee. Discussions were proceeding on the comparative cost of providing electricity by the proposed hydro-electric generating schemes published by the North of Scotland Board, and by the installation of additional thermal generating capacity elsewhere in

Scotland, and in the light of these comparative costs, the North of Scotland Board would decide whether to make the necessary formal inquiries into the hydro-electric schemes. A subordinate recommendation of the Mackenzie Committee was that special assistance should be provided to enable rural electrification in the north of Scotland to be speeded up and to link the islands with the mainland by submarine cable. Mr. Noble said that the North of Scotland Board considered that most of these cables would be needed only when the existing Diesel generating stations on the main islands had to be renewed, but had drawn up a programme for accelerating the present rate at which consumers in the more remote areas could be given supplies.

The Deer Bill

In moving the Second Reading of the Deer Bill in the House of Lords on June 28, Viscount Massereene and Ferrard pointed out that the reasons for the Bill were not entirely the same as those which led to the Deer (Scotland) Act, 1959, which followed the report of the Scott-Henderson Committee on cruelty to wild animals, although the clauses dealing with the avoidance of unnecessary cruelty to deer were essentially the same as the corresponding sections of the Scottish Act, but confined to English as opposed to Scottish law. There had been a great increase in the deer population of England and Wales following the increased acreage of timber, now reaching 600,000 acres, and this had altered the pattern of wild-life, while there had also been an increase in arable land. Further, especially in the past fifteen years, the number of weapons in private hands had greatly increased, and while motor-cars had made the countryside more accessible there was still no proper legislation in force to protect deer. Among those who had contributed to the preparation of the Bill besides its sponsors, the British Field Sports Society, Viscount Massereene mentioned the Forestry Commission, the Nature Conservancy, the Council for Nature and the Fauna Preservation Society. Clause 1 dealt with close seasons and provided a close season for stags and bucks from May 1 until July 31, but no close season was provided for the roebuck, and Viscount Massereene explained that the shorter season than that provided under the Scottish Act was due to the difference in habitat. He also pointed out that under Sub-sections of this Clause the Secretary of State was authorized to amend this Schedule by Order by the addition of any species not mentioned in that Schedule. This would enable other species of wild deer, such as the muntjac and the Chinese water deer, which appeared to be becoming indigenous, to be included. This Clause was the subject of some discussion in a debate in which the Bill was generally welcomed, and Lord Dowding and other speakers advocated that the close season should be advanced to February. Clause 2 empowers the Nature Conservancy to license such prohibited articles as stupefying drugs or muscle-relaxing agents with the object of taking deer alive for scientific or educational purposes. Controversy centred chiefly on the weapons Clause and was concerned essentially with the technicalities of prohibited weapons, both rifles and shot guns. The Bill was committed to a Committee of the whole House.

The National Ports Council

In moving a resolution in the House of Commons on July 10, welcoming the Government's statement of March 6, 1963, on the report of the Rochdale Committee of Inquiry into the Major Ports of Great Britain, the Minister of Transport, Mr. E. Marples, said that the Government fully shared the view expressed in the report as to the need for more research, both technical and operational, but no final conclusion had been reached as to the kind of studies needed and how they should be made. The first need was reconnaissance to supply a complete picture of the technical and operational research already in progress and how it was being conducted. The Lord President of the Council, after consultation with Lord Rochdale and the Minister of Transport, had arranged for such an investigation to be made, and Mr. Marples said that he would expect to receive advice from the National Ports Council on the need for economic research on particular problems. On July 9, Mr. Marples, in a written answer, gave the following names of those who had agreed to serve under the chairmanship of Lord Rochdale on the National Ports Council: Mr. E. D. Arney, J. H. Joyce, Ian W. Macdonald, Sir Eric Millburn, D. M. Robinson, E. G. Whitaker and L. T. Wright.

Expenditure on the Commonwealth Education Scheme

In a written answer in the House of Commons on July 9, the Secretary for Technical Co-operation, Mr. R. Carr, stated that expenditure on the Commonwealth Education Scheme, for which the Government had undertaken to make available up to £6 million during the five years ending in 1965, included provision for the supply of teachers, for which purpose about £1 million would be used, and so far nearly £700,000 had been committed.

The Royal College of Science and Technology, Glasgow

The annual report of the Royal College of Science and Technology, Glasgow, for the one hundred and sixty-sixth session, 1961–62, records a total of 1,997 full-time students, together with 1,203 part-time day and 1,343 evening students (Pp. 89. Glasgow: The Royal College of Science and Technology, 1963). The associateship of the College was conferred on 294 students, of whom 28 were in chemistry, 19 in metallurgy, 48 in civil, 102 in mechanical, 11 in chemical and 41 in electrical engineering. The titles of theses approved for the award of the associateship are listed and there are also lists of recent publications by members of the College and of industrial research reports issued during the year. Twenty-five members of the College obtained the degree of Ph.D. of the University of Glasgow and three the degree of M.Sc. 31 diplomas of membership for postgraduate study were awarded; the titles of theses for all these degrees and awards are also listed. Brief particulars of research in progress are included under the several departmental reports, but a full record is given in the *Research Report for the Session 1961–62*, which is published separately and also includes lists of the more important publications and of the titles of theses approved for higher degrees; these lists of publications are annotated (Pp. 43+4 plates. Glasgow: The Royal College of Science and Technology, 1963). A research group in elasticity has been set up in the Department of Mathematics, and sponsored industrial research for the South of Scotland Electricity Board, the British Shipbuilding Research Association, the Ministry of Aviation and the Cold Rolled Sections Association continued in the Department of Mechanical, Civil and Chemical Engineering, while work also continued on traffic engineering with reference to the traffic problems in Glasgow.

The British Hydromechanics Research Association

The fifteenth annual report of the British Hydromechanics Research Association, covering the year October 1961–September 1962, refers to exploration of the possibility of a closer link with an academic or research institution in a related field, and plans for expanding the laboratory (Pp. 40. Harlow: The British Hydromechanics Research Association, 1963). Research on centrifugal pumps included a study of the axial thrusts that act on some pump impellers and the behaviour of balancing vanes attached to the impeller or to the front-side wall of the pump casing. Low-pressure work on seals and glands is concentrated on elucidating the nature of the interfacial fluid film and the mechanisms involved in pressure generation within this film. Considerable pro-

gress is reported on the study of the power losses of various components of axial piston pumps and motors, and methods of designing hydrostatic slipper pads, pistons and valve plates; means have been devised to minimize the sum of the viscous-drag and flow-leakage losses. A large-scale model study has commenced involving the flow of water, ash and air, of an open channel installation designed for the rapid discharge of a railway train of ash wagons. The work on ejectors has been extended to include those in which both the driving and entrained fluids are compressible, and a programme has been written for the digital computation of initial downsurge at pump shutdown. Problems in the design of power stations which have been investigated relate to cooling-water systems and the ventilation of boiler-houses. A list of publications during the year is included, and application in advance for invitation to visit the Laboratory on the afternoons of September 11 and 12, when exhibits illustrating most phases of the Association's work will be shown, is invited from those interested.

The Lace Research Association

THE fourteenth annual report of the Lace Research Association for 1962 records that sixteen machines fitted with the beam thread-break indicator are now in regular use (Pp. 30. Bilborough, Nottingham: Lace Research Association, 1963). Moreover, although the prototype of a new device traversing the facing bar of the Leavers machine to detect holes caused through broken threads worked well, improvements made or in hand include a better driving system for the scanning head, facilities for increasing the number of scanning heads, and a means for pre-selecting the length of hole which will trip the warning signal. Measurements have been made of the various features relating to gap widths and packing density in brass-bobbin winding, and a technique of 'potting' bobbins with synthetic resin has been evolved which allows the bobbin to be radially sectioned without disturbing the lie of the yarns. Photographic techniques have been examined which are aimed at producing points at about 200 times magnification, so that individual filaments in the yarn can be counted, and thus the packing density in the bobbins checked. Considerable advance is reported in the project to mechanize the 'clipping' process in lace finishing and several different types of scalloping machine have been examined as to their suitability for scalloping Leavers lace. Small amounts of triallyl phosphate have been attached to cellulose by graft polymerization, but the flame-proofing achieved was insufficient to bring cotton net into the 'fabric of low-flammability' category. Trials of sodium borohydride as a bleaching agent showed that when used on cotton after hypochlorite bleaching improved fluidity figures are obtained, and it was also useful in cleaning heat-discoloured nylon. A report has been presented to the Council on recent work on lubrication.

Petroleum Consumption in the United Kingdom, 1962

FIGURES released by the Petroleum Information Bureau on behalf of the United Kingdom Petroleum Industry Advisory Committee in May 1963 reveal that demand for petroleum products in the United Kingdom in 1962 was 10·6 per cent higher than in 1961 (*U.K. Petroleum Industry Statistics: Consumption and Refinery Production, 1961 and 1962*. Pp. 8. London: Petroleum Information Bureau, 1963). If bunkering for ships engaged in foreign trade be excluded, total deliveries into consumption of all petroleum products amounted to 50,900,433 tons as against 46,014,950 tons in 1961. Consumption of motor spirit increased by 5·2 per cent, deliveries to dealers being 7 per cent up while those to commercial consumers dropped by 3·5 per cent, reflecting the continual change-over from petrol to diesel-engined commercial vehicles. Deliveries of DERV (diesel-engined road vehicle) fuel actually increased during the year by 7·1 per cent. The average temperature in 1962 was some 2° F below that of 1961 and to this fact is ascribed the considerable increase in demand for the 'black oils', gas/Diesel oil deliveries rising by 17 per cent, fuel oil by 13·4 per cent compared with the previous year. This weather factor also led to an increase in consumption of burning oil, which showed an increase of 16·3 per cent, due largely to the growing popularity of oil-fired central heating, which represented more than 50 per cent compared with 1961, also of free-standing space heaters the demands of which rose by 12·7 per cent. In agricultural operations, Diesel-engined tractors are steadily replacing the less efficient vaporizing-oil type, and this process is reflected in the decline of vaporizing-oil deliveries by 18·7 per cent. Regarding aviation fuel consumption, there was a slight decrease of 2·2 per cent compared with 1961; of a total of 2,108,348 tons, approximately nine-tenths of this comprised aviation turbine fuels, demand for which in 1962 amounted to 1,886,420 tons as compared with 221,928 tons for aviation spirit. Recession in industry and shipping, which account for nearly 60 per cent of all lubricants sold, was reflected in the lower demand for lubricating oils and greases, a decrease of 1·2 per cent compared with the 1961 figure. The use of liquid gases, propane and butane, by Gas Boards and industry is shown by the remarkable growth-rate of 42·6 per cent, deliveries being 294,163 tons compared with 206,285 tons in 1961. Finally, as might well be expected having regard to the phenomenal expansion of the petrochemicals industry, petroleum chemical feedstock deliveries were up by 23·5 per cent, 1,948,861 tons, compared with 1961.

Stable Isotopes of Oxygen

HIGH enrichments of both stable isotopes of oxygen have recently been achieved. Up to 99 atomic per cent of oxygen-18 has been available for some time in various chemical forms and has already been widely used in chemistry and biology as a tracer and as both target and projectile in nuclear studies. Oxygen-18 labelled compounds also have great potentialities in studies of isotope effects and spectral isotopic shifts. Oxygen-17 with a spin of 5/2 is the only isotope of oxygen which can be used for nuclear magnetic and electron spin resonance investigations. Enrichments of more than 10 atomic per cent oxygen-17 in water and 50 atomic per cent oxygen-17 in oxygen gas have recently been reached on a production scale in the Isotope Separation Plant of the Weizmann Institute of Science. These concentrations represent a 250-fold enrichment of oxygen-17 in water and 1,350-fold enrichment in oxygen gas. These materials are now available through YEDA Research and Development Co., Rehovoth, Israel. A booklet containing some pertinent references and a catalogue of materials enriched by oxygen-18 and oxygen-17 can be obtained from that Company.

Organ Pipes

CENTURIES of organ building have firmly established a preference for alloys of tin and lead as the best material for organ pipes, though in recent years to save cost zinc has been used with a sacrifice of some tonal quality. Acoustic research in the Physikalisch-Technische Bundesanstalt at Brunswick, by Drs. W. Lottermoser and J. Meyer, using pipes of 'lead' (lead 70 per cent, tin 30 per cent), 'tin' (tin 70 per cent, lead 30 per cent), copper, both electrolytic and fire-refined zinc and pine wood, has confirmed this distinctive acoustic characteristic of the different pipe materials, determined mainly by their damping properties. From the musical point of view, organ pipes should radiate harmonic tones uniformly in all directions and emit a minimum of discordant sounds due to eddies set up by the jet of air issuing between the tongue and lip. These cause not only strong whistling sounds—especially noticeable at the instant that the

pipe begins to sound—but also set up vibrations in the metal of the pipe which may bear no relation to the fundamental note. The more rigid the material the stronger are these effects; weaker ones, such as the tin–lead alloys, damping them out. The results show clearly the sharper tones due to the use of copper and particularly the hardness and musically disturbing notes produced by zinc. Wooden pipes yield softer notes and are specially suited to some special stopped pipes and flutes, while lead–tin alloy is best for those stops required to give a full, soft note. Of the materials examined, the 70 per cent tin + 30 per cent lead alloy is outstanding as the nearest approach to the ideal material for such use. Drs. Lottermoser and Meyer's results are summarized in No. 58 of *Tin and Its Alloys* (1963), published by the Tin Research Institute, and also in full in the February 1962 issue of *Metall* (p. 108).

Chemical Analysis of Fruit Juices: Standardization of Methods

The Scientific and Technical Commission of the International Federation of Fruit Juice Producers have set up a Sub-commission for the Standardization of the Chemical Analysis of Fruit Juices. Several European countries are represented on the Sub-commission and their recommendations have now been published (International Federation of Fruit Juice Producers. *Analyses*. Pp. 38. Wädenswil, Switzerland: Dr. Hans Lüthi, Sektion Getränkechemie und Biologie, Eidg. Versuchsanstalt für Obst-, Wien- und Gartenbau. 1962). Methods are described for the determination of specific gravity, alcohol, titratable acid, sugar, volatile and non-volatile acids and sulphur dioxide. In each case the details of the necessary apparatus, reagents and determination procedure are described in separate English, German and French sections. A useful feature is the inclusion of the degree of accuracy to which each result should be reported. In addition the general principle of each of the procedures is briefly indicated, but, as usual with standard methods, the interpretation of the results is not discussed. The publication is in loose-leaf form so that supplements can be added when necessary. The introduction states: "This standardization of our chemical methods is very urgent, especially with regard to international negotiations".

Survey of Hospital In-Patients in Britain

The full report on the *Hospital In-Patient Enquiry for the Year 1959* has recently been published by the Registrar General (H.M.S.O. £1 7*s*. 6*d*.). The inquiry is based on forms completed by hospitals for every tenth patient discharged or died, the selection of patients being at random. The inquiry was originally begun in 1949; but until 1957 it was based on hospitals whose co-operation was voluntary. Since 1957 all non-psychiatric hospitals in England and Wales have been included, though some cases, mainly private and staff patients, have been excluded from the analysis. This consists of tables, showing the number of deaths and discharges (spells) and the associated rates by various characteristics, such as sex, age, region, diagnostic group, and department of hospital in which the treatment took place. There is also a special and detailed analysis of maternity cases. The figures are extremely detailed, and defy any attempt at summarizing within a short space. They do, of course, relate to spells in hospital, rather than to individual cases, and no attempt has been made to use the information about the occupation of the patients or the industry in which they worked which is collected on the forms. Many other possible cross-tabulations will no doubt occur to users of the material, and the foreword invites interested persons to inquire at the General Register Office for additional information which may be available.

Tenth International Botanical Congress, Edinburgh

The tenth International Botanical Congress is to be held in Edinburgh during August 3–12, 1964. Some ten thousand preliminary circulars have been dispatched to botanists all over the world. The second Congress circular, which gives details of the scientific programme and the full programme of botanical excursions, is due to be dispatched in August or early September. Copies of the circular can be obtained from the Secretary (Executive Committee), Tenth International Botanical Congress, 5 Hope Park Square, Edinburgh 8.

The Night Sky in September

Full moon occurs on Sept. 3d. 19h. 34m. U.T. and new moon on Sept. 17d. 20h. 51m. The following conjunctions with the Moon occur: Sept. 2d. 05h., Saturn 1° N.; Sept. 6d. 07h., Jupiter 4° N.; Sept. 21d. 03h., Mars 5° S.; Sept. 29d. 12h., Saturn 1° N. In addition to these conjunctions with the Moon, Mars is in conjunction with Spica on Sept. 1d. 00h., Mars being 2° N. Mercury, Venus and Mars are too close to the Sun for easy observation. Jupiter rises at 20h. 00m., 19h. 00m. and 18h. 00m. on September 1, 15 and 30, respectively. It is in Pisces, its stellar magnitude is −2·4 and its distance from the Earth on September 15 is 375 million miles. Saturn sets at 3h. 20m., 2h. 20m. and 1h. 20m. at the beginning, middle and end of the month, respectively. It is in Capricornus, its stellar magnitude is + 0·6 and its distance from the Earth on September 15 is 840 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Sept. 5d. 0h. 36·9m., 30 Psc. (*R*); Sept. 7d. 22h. 49·3m., μ Cet. (*D*); Sept. 7d. 23h. 48·7m., μ Cet. (*R*); Sept. 26d. 20h. 45·2m., 154 B. Sgr. (*D*). *D* and *R* refer to disappearance and reappearance, respectively. The autumnal equinox occurs on Sept. 23d. 18h.

University News : Belfast

The following appointments to lectureships have been announced: Dr. R. M. Hobson (physics); Dr. M. A. Leonard (inorganic and analytical chemistry); Dr. P. J. S. Boaden (zoology); Dr. J. M. Dunbar (bacteriology). Mr. C. D. Kemp has been appointed to a senior lectureship in statistics.

Bristol

Dr. F. G. A. Stone, reader in inorganic chemistry in Queen Mary College, London, has been appointed to the chair of inorganic chemistry. Dr. J. M. Ziman, lecturer in physics, University of Cambridge, has been appointed to the chair of theoretical physics. The following appointments to lectureships have been announced: J. F. Harper (mathematics); Dr. G. M. Jarman (zoology); A. Keller (physics); Dr. K. Lederis (pharmacology); D. Lovelock (mathematics); Dr. J. MacMillan (organic chemistry); Dr. A. Simpson (aeronautical engineering); Dr. M. A. Sleigh (zoology).

Cambridge

Dr. L. Weiskrantz, of King's College, assistant director of research in experimental psychology, has been elected to a fellowship (Title *A*) of Churchill College as from October 1.

Cardiff

Dr. L. Crombie, at present reader in organic chemistry at King's College, London, has been appointed to the chair of organic chemistry at University College of South Wales and Monmouthshire.

East Anglia

Dr. R. T. Joy has been appointed lecturer in the School of Biological Sciences.

Leeds

DR. F. A. GOLDSWORTHY, at present lecturer in mathematics at the University of Manchester, has been appointed to a second chair of applied mathematics. Dr. A. W. Goldie, at present reader in algebra at King's College, Newcastle upon Tyne, has been appointed to a second chair of pure mathematics.

London

PROF. F. K. HARE, professor of geography and meteorology at McGill University, has been appointed to the chair of geography tenable at King's College. Mr. H. D. Ritchie, reader in surgery at the London Hospital Medical College, has been appointed to the chair of surgery tenable at that College. Dr. D. H. Michael, lecturer at University College, has been appointed to the readership in applied mathematics tenable at that College. Titles of reader have been conferred on the following: Dr. E. M. Deeley (electrical engineering), in respect of his post at King's College; Miss Vera I. Evison (archæology of the Anglo-Saxon period), in respect of her post at Birkbeck College; Mr. A. R. Ilersic (economic and social statistics), in respect of his post at Bedford College; Dr. N. Waloff (animal ecology), in respect of her post at the Imperial College of Science and Technology; Dr. E. M. Yates (geography), in respect of his post at King's College.

THE annual report for 1961–62 of University College, London, includes the report of the Chairman of the College Committee and the Provost, lists of publications by members of College Departments, August 1, 1961–July 31, 1962, as well as particulars of staff, higher degrees awarded, and College awards to students (Pp. 105. London: University College, 1963). A Development Council set up to further a comprehensive long-term programme has recommended maximum utilization of the present site as a first step. Student accommodation remains a major concern, and of the 3,119 full-time students, 1,708 live in lodgings, often at a considerable distance, and only 610 in University halls of residence. The number of postgraduate students increased by 5 per cent to about 1,100. Expenditure on research increased by £92,424 to £408,224.

Rehovoth

THE report of the Weizmann Institute of Science, Rehovoth, for the two years 1960–61 contains brief accounts of the work in progress in some seventeen sections together with lists of publications, including patents, and lists of scientific staff (Pp. 151. Rehovoth, Israel: The Weizmann Institute of Science, 1963). Major building activity is at present centred in biology, but a new focus of collaborative research in the chemistry and physics of the solid state is being created. Besides plans for construction of a high-speed transistorized computer for applied mathematics, enlargement of the present Van de Graaff accelerator is contemplated.

Swansea

THE following appointments have been made for the session 1963–64: *Readers*, Dr. D. A. Long (chemistry), Dr. K. C. Rockey (civil engineering); *Senior Lecturers*, A. P. Greenough (metallurgy), Dr. E. Naylor (zoology), G. L. Rees (economics), Dr. J. A. Sandover (civil engineering); *Lecturers*, Dr. R. H. Jones (physics), Dr. D. Betteridge (chemistry), C. Tomlinson (geography), Dr. B. Atkinson (chemical engineering).

Announcements

THE following officers of the Canadian Biochemical Society have recently been elected: *President*, J. H. Quastel; *Vice-President*, L. Berlinguet; *Secretary*, H. D. Branion; *Treasurer*, R. M. Hochster; *Councillors*, J. M. R. Beveridge, S. H. Zbarsky and P. B. Hagen.

A MEETING on "The Rheology of Clays and Fine Particle Suspensions" will be held by the British Society of Rheology at the University of Keele during September 26–27. Further information can be obtained from J. F. Hutton, Shell Research, Ltd., P.O. Box 1, Chester.

A SYMPOSIUM on "The Ellipsometer and its Use in the Measurement of Surfaces and Thin Films" will be held at the National Bureau of Standards, Washington, during September 5–6. Further information can be obtained from Elio Passaglia, National Bureau of Standards, Washington 25, D.C.

A COURSE on "The Genetics and Physiology of Bacterial Viruses" will be held in the International Laboratory of Genetics and Biophysics, Naples, during September 18–October 12. Further information can be obtained from the Laboratorio Internazionale di Genetica e Biofisica, Casella Postale 104, Napoli.

THE fourth British Congress on the History of Medicine and Pharmacy entitled "The Evolution of Pharmacy in Britain" will be held in the University of Nottingham during September 20–23. Further information can be obtained from Dr. F. N. L. Poynter, Wellcome Historical Medical Library, the Wellcome Building, Euston Road, London, N.W.1.

THE Plant Phenolics Group is widening its scope to include other plant constituents. A symposium on "Comparative Biochemistry of the Leguminosae" will be held during September 10–11 at the John Innes Institute, Hertford, and will include nitrogenous compounds as well as phenolics. Further details can be obtained from the honorary secretary, A. H. Williams, Research Station, Long Ashton, Bristol.

THE third annual meeting of the Plant Phenolics Group of North America will be held in the University of Toronto during September 6–7. The programme will include a symposium on "Aspects of Plant Phenolic Chemistry". Further information can be obtained from Dr. V. C. Runeckles, Imperial Tobacco Company of Canada, Ltd., P.O. Box 6500, Montreal, Quebec.

A CONFERENCE on "Some Aspects of Surface Behaviour", arranged by the Materials and Testing Group of the Institute of Physics and the Physical Society, will be held at the University of Bristol during September 16–17. Subjects under discussion will include: surface adsorption, diffusion and energy; macroscopic effects involving surfaces, for example, friction, stress corrosion and fatigue. Further information can be obtained from the Administration Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A VACATION course in "The General Theory of Electrical Machines", arranged by the Electrical Engineering Department of the Imperial College of Science and Technology, London, will be held at the College during September 16–20. The course will provide an introduction to modern methods of calculating the performance of d.c. and a.c. machines under any conditions of operation. Further information can be obtained from B. J. Prigmore, Electrical Engineering Department, Imperial College of Science and Technology, London, S.W.7.

A CONFERENCE on "Cellular Control Mechanisms and Cancer", organized under the auspices of the Commission on Cancer Research of the International Union Against Cancer and the Netherlands Cancer Institute, will be held in Amsterdam during September 9–13. Subjects under discussion will include: genetic control of protein synthesis; mechanisms of cell differentiation; growth regulation; structure and function of tumour cells; carcinogenic agents. Further information can be obtained from Prof. O. Mühlbock, Netherlands Cancer Institute, Antoni van Leeuwenhoek-Huis, Sarphatistraat 108, Amsterdam *C*.

SPEEDING THE PACE OF TECHNOLOGICAL DEVELOPMENT IN THE PETROLEUM INDUSTRY

PERHAPS in no other branch of applied science has fundamental research, both in the field and in the laboratory, borne so much fruit in so short a time as that of petroleum technology. During the past thirty years, since the first World Petroleum Congress, the evolution of the industry has not only been underlined by its magnitude and spectacular accomplishments but also by the complexity of the problems, both human and technical, that such rapid advancement of our knowledge of this technology has engendered. It is, indeed, timely that attention has been directed to the more philosophical aspects of the trend of modern research in the industry and its possible limitations if certain human factors are not taken into account. In no more appropriate setting than that of the sixth World Petroleum Congress held in Frankfurt during June 19–26 could the facts and fears be proclaimed and few are better qualified than Mr. John Loudon, president of the Royal Dutch Petroleum Co. and senior managing director of the Royal Dutch/Shell Group of companies, to state the case as it really exists.

In his executive position in the industry and with all the experience he brings to bear, although he disclaimed at the outset of his address to the Congress: "any competence as an expert in science and technology", Mr. Loudon touched on some of the most sensitive aspects of planned research in the industry which have in recent years impressed themselves on the more far-seeing people concerned with guiding research teams and particularly with financing the adventures they are called on to undertake. For example, nobody could disagree with his contention ". . . that the limiting factor in science and technology is the number of creative individuals who provide the ideas from which all novelty comes". Again: "We have become so accustomed to thinking in terms of money and to assuming that more money will get us more of anything that is desired that we sometimes lose sight of other limitations. In research we may already have reached the state of diminishing returns for our investment —not only of industry but of society as a whole". Much has recently been heard of the lure of some of British top-grade scientists abroad, tempted by higher remuneration and alleged superior research facilities. But this competition is by no means confined to prospects overseas. The influence of Government Departments in Britain, quite apart from foreign interests, concerned with atomic energy, space research and national defence projects, for example, is felt in their ". . . competing for the limited available talent not only with industry and with universities but with each other". Mr. Loudon went on to say: "It is evident that much of the effort, both military and civilian, has been devoted not to really original concepts but to the rapid exploitation in many different laboratories of the few ideas that are occasionally produced by brilliant individuals".

The trend of policy of the Royal Dutch Petroleum Co. can be discerned from the statement that economically the profitability of industrial research, while still high, is decreasing due, apparently, to the increasing number of instances of simultaneous inventions; these complicate patent portfolios and render it difficult to decide whether money should be invested for projects based on technical novelty or superiority which could well turn out to be illusory. Much the same precepts, we suspect, are influential in the research policy of the other major oil companies at the present time. Thus, both the technical and economical difficulties ahead can, Mr. Loudon argued, only be solved by using available brainpower efficiently. "In our efforts to truly speed the pace of technology in the petroleum industry we must try to do two things: first, by supporting and undertaking basic research increase the number of new ideas; secondly, encourage our applied scientists and our commercial staff to be adventurous in their choice of new processes and products for development. And as citizens, we should ponder the question of whether the world can long afford an inefficient use of our previous asset of brainpower".

Only creative human talent can provide the science and technology needed to-day. That talent is limited, as is the case throughout the world. It is not enough to seek refuge in criticism of our present educational systems, on one hand deploring the fact that not enough scientists and technologists are being trained to meet the needs of our culture, or, alternatively, that science and technology are being over-stressed at the expense of the humanities, to the future detriment of that culture. Mr. Loudon concluded this most stimulating discourse with a statement of his belief ". . . that with a modicum of good sense and a minimum of dogma the paradox (in the above opposing views) vanishes. Science and the humanities are by no means incompatible. . . . In our business particularly, we need men trained in the sciences with an understanding of the humanities, men trained in the humanities with an understanding of science". Moreover, ". . . the rare individuals who can master both worlds are those who are contributing most to the effective use of technology. Such men are also continuing to aid the universities, giving lectures, serving on advisory committees, sometimes even leaving us to take up permanent posts. And by prompt publication of our basic research we are contributing to the body of scientific knowledge". H. B. Milner

THE INTERNATIONAL SCIENTIFIC RADIO UNION

FOURTEENTH GENERAL ASSEMBLY

By Dr. R. L. SMITH-ROSE, C.B.E. (President)

PREPARATIONS are now well in hand for the fourteenth general assembly of the International Scientific Radio Union (URSI) which will be held at the Takanawa Prince Hotel, Tokyo, during September 9–20. For the past two years a large committee, appointed by the Science Council of Japan, has been preparing the general arrangements under the guidance of a smaller Executive Board, of which Prof. I. Koga, vice-president of the International Scientific Radio Union, is the chairman, and Prof. S. Okamura the secretary. The detailed programme for the assembly is being organized by six small committees including two dealing with the scientific and ladies programmes respectvely.

The forthcoming general assembly is noteworthy in that it will mark the fiftieth anniversary of the formation of the International Scientific Radio Union at a small

preliminary meeting in Brussels attended by nine scientists during October 1913. A second meeting was held during April 1914, and was attended by fourteen scientists from six European countries. After the First World War the Union was one of the first to be organized in 1919 under the general supervision of the International Research Council, which in 1931 was replaced by the International Council of Scientific Unions. The other three Unions were the International Astronomical Union, the Union of Geodesy and Geophysics and the Union of Pure and Applied Physics.

The first General Assembly of the International Scientific Radio Union was held in Brussels in 1922, and was followed by others in Washington (1927), Brussels (1928), Copenhagen (1931), London (1934) and Venice (1938). After an interval during the Second World War, the activities of the Union were resumed at the seventh general assembly held in Paris in 1946; and this was followed at two-year intervals by meetings in Stockholm, Zurich, Sydney and The Hague until 1954. On the last occasion it was decided to change the interval between assemblies to three years; and the twelfth and thirteenth were held in Boulder and London in 1957 and 1960 respectively. The attendance on the latter occasion was about 830, of whom nearly 450 were official delegates, and 150 were observers from the host country interested in various aspects of the scientific programme. There were also a small number of invited guests, and some 200 members of the families of delegates and observers.

The International Scientific Radio Union is one of the fifteen scientific bodies which now adhere to the International Council of Scientific Unions and it is in effect a federation of the national scientific academies in 28 countries throughout the world. The objectives of the Union are to promote and organize radio research requiring international co-operation, to encourage the development of such agreed methods of measurements as may be required for the investigation of any radio phenomena with particular reference to those associated with the Earth, its atmosphere and outer space. The influence of the Sun and of general and geophysical conditions on the radio phenomena has naturally required close collaboration between the four Unions referred to here. In more recent years, this collaboration has been extended to include the International Committee on Space Research (COSPAR) which was formed in 1958 and has recently held its fourth international symposium in Warsaw (May 1963).

To return to the forthcoming general assembly of the International Scientific Radio Union, the scientific programme is being organized under the existing seven commissions, the titles and present chairmen of which are: (1) radio standards and measurements methods (Dr. U. Adelsberger); (2) radio and troposphere (Mr. J. Voge); (3) ionospheric radio (Mr. J. A. Ratcliffe); (4) radio noise of terrestrial origin (Prof. R. A. Helliwell); (5) radio astronomy (Sir Bernard Lovell); (6) radio waves and circuits (Mr. J. Loeb); (7) radioelectronics (Prof. W. G. Shepherd).

The wide range of scientific activities in various parts of the world in most, if not all, the aforementioned fields has made it necessary to restrict the scope of the items selected for discussion at each of the sessions which will be available to the commissions. Accordingly, each chairman has formulated the subjects to be discussed by his commission and has invited some well-known authorities to prepare introductory papers for presentation at Tokyo. These papers, together with a summary of the main features of the discussion thereon, will be published in the *Proceedings* of the general assembly. In accordance with past practice, no uninvited papers will be considered for acceptance. As some of the subjects selected for discussion are of common interest to more than one commission, arrangements have been made in the programme for joint meetings and also for meetings of the commissions with other committees of the Union such as that on space radio research or with the International Committee on Geophysics. The latter body, incidentally, has replaced the former committee which organized the co-operative scientific work during the International Geophysical Year of 1957–58 and afterwards, and it has recently been actively engaged in formulating the corresponding programme for IQSY, the International Year of the Quiet Sun (1964–65).

At the general assembly in London in 1960, representatives from the International Scientific Radio Union were appointed to its parent body—ICSU—as well as to various specialist committees in which the Union is associated with the interests of other unions or committees in such subjects as the ionosphere, radio meteorology, solar and terrestrial relationships, space research and the allocation of radio frequencies for radio astronomy and space science. In this way, full collaboration is maintained between scientists in all parts of the world engaged in research in adjacent fields concerned with the Earth and its atmosphere, the Sun, the planets and outer space. Meetings of these committees will be called as may be appropriate during the general assembly, taking advantage of the presence in Tokyo of the various interested scientists.

During the Assembly various formal receptions are being arranged by the Japanese Committee, and some visits of technical interest will be offered to the visitors. A special programme for ladies has also been distributed. After the assembly, a four-day tour is available to Kyoto and Nara, towns which are of historic interest because they were former capitals of Japan.

MULTIPLE MOLECULAR FORMS OF ENZYMES AND THEIR USE IN CLINICAL DIAGNOSIS

A SYMPOSIUM on "Multiple Molecular Forms of Enzymes" organized by the University of Ghent in collaboration with the Belgian Society for Clinical Chemistry, was held in Ghent on April 27. It was the first of its kind in Europe, and the interest it arose can be judged from the fact that several weeks before the deadline for registration, the limiting number of 150 participants had already been reached. Representatives from most west European countries were included among the speakers and also several from the United States.

The meeting was concerned with the structure of isoenzymes and with their clinical uses. As to the first, E. Appella (Centre de Chimie Macromoléculaire, Strasbourg) presented data defining the physical properties of lactic dehydrogenase 1 (LDH1) and LDH5 (beef tissue) and their amino-acid composition. All available evidence tends to support the hypothesis formulated by the author together with Markert that LDH1 is composed of four identical sub-units, while LDH5 is composed of four identical sub-units of another type; LDH2, LDH3 and LDH4 correspond to combinations of each of these sub-units into groups of four. These hybrid forms can be produced *in vitro*: following dissociation into sub-units of pure LDH1 and LDH5 molecules in a medium of high ionic strength, randomized re-association occurs on removal of the sodium chloride.

M. D. Poulik (Child Research Center, Detroit) took ceruloplasmin as an example of a second class of isoenzymes

—the polymer type. He advocated the use of electrophoretic media differentiating between size of the molecules; experiments with such dissociating substances as urea and SH-compounds also give useful information concerning the number and nature of the sub-units. K. Van Asperen (Laboratory for Insecticide Research, Wageningen) stressed the importance of genetic investigations in drawing up the isoenzyme concept. He pointed out that from his work on esterases in the house-fly it is clear that a third class of isoenzymes occurs where the difference is one in primary structure. In support of this view, M. Rabaey and H. Gysels (Department of Ophthalmology and Zoology, University of Ghent) described the multiplicity of myoglobins in vertebrates. Myoglobins can be considered isoenzymes since they all have peroxidase activity.

Several speakers surveyed the method for isoenzyme separation which they developed. H. J. Van der Helm (Provinciaal Ziekenhuis, Santpoort) discussed electrophoretic methods. He made interesting comments on specific problems that are encountered when a conventional histochemical technique is applied to the detection of enzyme activity in electrophoresis slabs. Here, one is more concerned with quantitative aspects than with precise localization. Eluting effects should be reduced by choosing a thick layer for electrophoresis, but rapid contact with the reagents is obtained if thin layers are used. Both requirements can be met in an agar medium. G. A. Whyley (University College, London) used cellulose acetate electrophoresis followed by elution of the segments. H. Barnett (South London Hospital for Women, London) favoured the tetrazolium procedure for direct staining of the cellulose acetate strips. She described two types of 'nothing' reactions. The first occurs in the presence of tetrazolium and phenazine methosulphate and results from reduction of the tetrazolium salt by —SH groups of proteins. The second requires in addition the presence of NAD and seems to be enzymatic, but occurs without any addition of substrate.

Column chromatography on DEAE cellulose was utilized by S.-I. Walter (Medizinische Universitäts-Klinik, Heidelberg) for separation of LDH isoenzymes and by B. Schobel (Medizinische Universitäts-Klinik, Vienna) for isolation of leucine aminopeptidase (LAP) isoenzymes. Walter also used a simple batch procedure, developed together with Hess for detecting LDH5 in human serum. The procedure is rapid but gives only a 'yes' or 'no' answer.

J. H. Wilkinson (Westminster Medical School, London) commented on a new procedure for assay of LDH isoenzymes. He found, together with Rosalki, that LDH1 has a much higher activity against α-ketobutyrate than LDH5. Thus an assay of LDH activity is made with each of these substrates and an index established which reflects changes in the isoenzyme pattern. The procedure proves especially valuable in the follow-up of myocardial infarction.

Another indirect procedure depending on selective thermal inactivation of LDH5 was described by H. Wust (Medizinische Universitäts-Klinik, Erlangen). The serum is heated for 30 min at 56° C. If more than 40 per cent of the activity disappears this indicates the presence of LDH5. However, several environmental factors, especially protein concentration and *p*H, tend to render this test less reliable.

Clinical applications were introduced by E. S. Vesell (Rockefeller Institute, New York), who warned against overestimating the specific diagnostic value of LDH isoenzyme determination. Similar patterns may be observed in sera from patients with different, unrelated disease. An increase in serum LDH5 is found not only in liver injury but also in some cases of acute arthritis and of dermatomyositis. In particular, shock, both hæmorrhagic and endotoxic, may liberate LDH from various tissues and thus distort the pattern from that expected for an uncomplicated disease.

H. A. Zondag (St. Elizabeth's Gasthuis, Haarlem) summarized the experience he collected from 4,000 determinations of the LDH isoenzyme pattern (agar-gel and 'Nitro-BT' method) in serum and other body fluids. He distinguished three main patterns: that of acute myocardial infarction (high LDH1), that of acute hepatic necrosis (high LDH5) and that of malignancy (high LDH2, 3, 4). The pattern of acute myocardial infarction has the highest clinical significance. Samples should not be stored in the frozen state since LDH5 may then be inactivated. U. C. Dubach (Medizinische Universitäts-Klinik, Basle) used thermal inactivation at two temperatures for differentiation between LDH isoenzymes. The method proved especially useful for follow-up of myocardial infarction, also for the diagnosis of pulmonary infarction and of primary myopathies. In the diagnosis of liver diseases results were less encouraging. L. J. Denis (Medical College of Virginia, Richmond) used agar-gel electrophoresis combined with the tetrazolium method for LDH analysis in malignancy. In cases of prostatic carcinoma in relapse an increase of serum LDH5 is regularly found. S. B. Rosalki (Kingston Hospital, Kingston upon Thames) investigated the isoenzymes of alkaline phosphatase, LDH and leucine aminopeptidase (LAP) in pregnancy. L. Pagliaro (Clinica Medica Generale, Palermo) used the Rosalki–Wilkinson test and obtained encouraging results. In muscular dystrophy the index pointed to an unexpected increase of LDH1. In the discussion it was made clear that this shift is to be explained by the modification in the LDH pattern of dystrophic muscle as described by Wieme and Herpol using agar-gel electrophoresis. G. Schapira (Hôpital des Enfants-Malades, Paris) reported on the changes in the LDH pattern of dystrophic muscle as revealed by starch-gel electrophoresis. The pattern recalls that of fœtal muscle. This suggests the occurrence of an arrest in the development of certain muscle proteins. J. Herpol (Kinderkliniek, University of Ghent) studied 150 normal children for the LDH serum pattern. The distribution was found to be similar to that in adults. In some cases a value higher than 75 per cent was found for LDH1; total LDH activity was then generally low.

Several other types of isoenzymes were also discussed for their clinical value. Malate dehydrogenase (MDH) was studied by M. Van Sande (Instituut voor Tropische Geneeskunde, Antwerpen) and proved of little diagnostic value. Despite separation into some nine fractions, all tissues tend to exhibit the same pattern. Leucine aminopeptidase was investigated by F. W. Wewalka (Medizinische Universitäts-Klinik, Vienna). Modifications in the serum pattern (starch-gel electrophoresis) mainly concern the appearance of new fractions. In liver disease modifications appear in the slow area. In pregnancy a new fraction of intermediate mobility is found. No direct relation with corresponding tissue fractions is manifest. This point was confirmed by R. Delcourt (Institut Médical, Ixelles), who also directed attention to the possible interference from inhibitors. A. J. Van Triet (Antoni van Leeuwenhoekhuis, Amsterdam) studied LAP isoenzymes in urine and found that in reticulosis a fraction is present that has a somewhat lower mobility than that usually found.

Alkaline phosphatases seem to constitute a promising field for isoenzyme analysis. B. N. Jensen (Psychiatric Institute, Aarhus) found three alkaline phosphatases in serum (electrophoresis on a polyvinyl chloride block). The ratio between the slowest and the intermediate form constitutes an index that serves to separate patients with liver disease (low index) from those with bone involvement (high index). W. G. Haije (Radiotherapeutisch Instituut, Rotterdam) used agar-gel electrophoresis for detecting physiological or pathological bone formation (increase of slowest) and for detecting liver disease (increase of most rapid fraction). The method seems especially interesting for detection of liver metastases.

Those present at the symposium agreed that: (1) The isoenzyme concept should be kept broad with a definition that could be given as follows: "different proteins with similar enzymatic activity". (2) Determination of LDH isoenzymes already now occupies a useful place in the clinical laboratory. (3) Direct histochemical procedures are preferable, but among indirect methods the Rosalki–Wilkinson test deserves special attention. R. J. WIEME

THE EAST AFRICAN ACADEMY

FIRST SYMPOSIUM AND INAUGURAL ANNUAL GENERAL MEETING

NEARLY three years since the idea was first put forward, the East African Academy came into being by the ratification of its constitution at Kampala in February 1963. Four months later, during June 14–17, the first symposium and annual general meeting was held at which more than 120 scholars, including eight delegates (representing the Royal Society of London, the Japanese Academy of Sciences, the Weizmann Institute of Science, and the U.S. National Academy of Sciences) attended. Messages of greetings and good wishes, apart from the aforementioned institutions, came from the U.S.S.R. Academy of Sciences, the Academia Sinica, the American Academy of Arts and Sciences, and from individuals and local organizations.

In many ways the East African Academy shows interesting characteristics. It is a regional, rather than a narrowly national, academy—covering the four East African countries of Kenya, Tanganyika, Uganda, and Zanzibar; it takes all departments of learning within its purview; apart from the usual aims of national academies, namely, the promotion of learning and the dissemination of knowledge, the Academy will take as its first-priority objective "to encourage scientific, technological and other advanced training within East Africa and to find ways and means for such training elsewhere"; and, because the Academy regards research by its members as one of its most important activities, it has already appointed a powerful four-man committee to be responsible for devising and taking immediate action on a policy for sponsoring research programmes, approving other research projects, selecting candidates for research fellowships, and handling research funds.

Two whole days were devoted to the symposium meetings, at which twenty-nine papers were read representing general themes (5), physical and chemical sciences (6), biological sciences (10), and arts and social sciences (8). The opening address was delivered by Dr. H. H. Storey, as a member of the Academy, on "East African Research on Plant Virus Diseases". After dealing with the history of virus research for the past seventy years briefly, he emphasized the contribution of East African work to virology by reviewing the investigation on cassava mosaic, groundnut rosette, and maize streak—all three being entirely African plant virus diseases. Finally, he demonstrated how the work on the obligate relationship between arthropod vector and virus has contributed to our fundamental knowledge of the vector–parasite association.

Prof. L. C. Beadle ("Inland Waters of East Africa as a Field for Fundamental and Applied Research") considered that East Africa presents particular problems because of its geological history, and the mode of origin of its lakes since the Miocene has provided a great stimulus for the evolution of new species of animals, for example, 400–500 species of fish are endemic. Factors which determine breeding seasons are more problematical in tropical environment: for example, there is a correlation with the onset of rain, and there seems to be an internal hormonal rhythm. The lake bottom is highly reducing, and it is suggested that it might be possible to pump up deep water in order to increase the circulation of organic matter (as the Belgians are already attempting in regard to Lake Kivu).

Glynn Isaac ("Olorgesailie: a Study of the Natural History of a Pleistocene Lake Basin and an Early Stage in Human Cultural History") affirmed that East Africa, particularly during the past thirty million years, is comparatively well endowed with basins containing deposits of the largest unbroken fossil record, later made available by tectonic disturbances followed by erosion. East Africa, therefore, appears to have been a centre of cultural and physical evolution. Olorgesailie Lake Basin in the Kenya section of the Rift Valley offers a good opportunity for such Quaternary research: he outlined the geological circumstances of the basin, and attempted a preliminary reconstruction of the environment of the basin 100,000–200,000 years ago, and of man's (supposed) activities in relation to it.

J. Gitau ("Importance of Soil Fertility and Fertilizer Use in Kenya, with Special Reference to African Farmers") stated that farmyard manure has been used from early times, but that this is increasingly becoming difficult in Kenya owing to the limitation of available land to peasant farmers. Hence, the use of artificial fertilizers offered a solution. This, however, raised the vital question of cost; and it was suggested that, as one of their important services, co-operatives should shoulder the responsibility of buying and distributing fertilizers.

Dr. Z. Subarsky ("Operation Ecology") described how a private committee was recently formed to rectify a state of affairs in biology teaching in East African schools in which the syllabuses, text-books, methods, and sometimes even type specimens for practical classes are imported from abroad. The committee is making an ecological classification in the form of a series of maps (physical, geological, climatic, and vegetational) on which schools will be marked. This procedure will facilitate selection of type specimens for particular topics in the syllabuses.

Physical and Chemical Sciences

L. A. J. Williams ("Geology of the Narok District of Masailand") described the mapping in reconnaissance style of this area, and included a summary of the exposed geological successions, maximum thicknesses, and some of the principal tectonic and physiographic events in the area. The talk was followed by that of Miss M. Lindley ("Notes on the Hydrology of the Mara–Narok Area"), who considered the relatively meagre hydrological records available of Masai areas. From these, she made the following tentative conclusions: the 49-year (1913–62) mean rainfall is 28·29 in., the 1933–49 period was one of generally below-average rainfall (24·0 in.), the 1950–53 period one of varying rainfall, and the 1954–62 period was a wet one (27 per cent above the mean). November–May is the wet period, but no month is free from the risk of drought; on the other hand, the pattern of evaporation through the year fluctuates much less than that of rainfall. She came to the conclusion that the average rainfall left no excess moisture for streamflow or replenishment of water stores. P. H. Temple ("Raised Features along the Southern Shoreline of Lake Victoria") noted the presence of extensive deposits of lacustrine sands and clays, now considerably above the present level of the Lake; and he offered speculations as to their significance.

Prof. M. Crawford ("Chemical Problems concerning Lemon Grass") stated that *Cymbopogon citratus* gives a 0·3 per cent yield of oil, and, by steam distillation, 80 per cent of the latter is found to be citral. The Uganda Development Corporation is taking this as an industrial proposition, extracting citral for flavouring, perfumery, and the manufacture of vitamin A. The biogenesis of citral is unknown, but the recent fall of citral content of lemon grass to 65 per cent is tentatively explained as related to age of the grass at the time of gathering.

Starting from the Appleton–Hartree formula, which gives the relationship between the refractive index of the ionosphere (itself essentially determined by the two factors of electron density and the Earth's magnetic field) and other quantities, S. Amer ("A Theoretical Method of Determining the Electron Density Profile of the Ionosphere") considered that the problem of determining the electron density profile is reduced to the determination of the refractive index as a function of altitude. Calculations, using data collected by measuring properties of radio waves transmitted from a satellite and received by a fixed observer on the Earth's surface, showed that the refractive index is a function of radial distance, that the Appleton–Hartree formula determines the electron density profile of the ionosphere, and that the Faraday rotation avoids any ambiguity due to birefringency of radio waves.

Biological Sciences

Dr. J. W. Kibuka-Musoke ("Antibodies and Low Temperatures") reported an important effect of exposure of the human body to low temperatures, in which antibodies with hæmagglutinating properties are found. In several recent cases in Uganda, the thermal limits of these antibodies were such as to produce venous thrombosis, often leading to gangrene. Genesis of these 'cold' antibodies is unknown, but they have been isolated. A vital aspect of the problem associated with the Miridae, a family of plant bugs containing extremely important crop pests, is that of the feeding process itself and of how this leads to the formation of characteristic lesions. Thomas R. Odhiambo ("Restatement of the Mirid Problem") gave a critique of the major researches on this subject. He suggested that it is the injection of salivary proteases into the feeding punctures which leads to the primary Mirid lesion. It was further proposed that "the salivary glands have the genetic potentiality of producing proteases (and other enzymes); but that whether or not this potentiality is translated into actual production of the enzymes depends on the kind of diet utilized". This proposal is thus linked to the wider problem of enzymatic adaptation. Prof. D. S. Kettle ("The Assessment of Biting Fly Population by Means of Biting Rates") listed the many sources of variation present when recourse is had to a direct measurement of the biting rate as a method of assessing the size of biting-fly population. Quasi-factorial experiments were described in which three Jamaican biting-fly species were caught simultaneously from an arm or leg by 4 individuals, in 4 positions, for 4 consecutive periods of 15 min each. It was found that all these factors influenced the catches, that the four weather factors investigated accounted for 88 per cent of the variation, wind speed and air temperature alone accounted for over 85 per cent, light intensity played merely a minor part, and saturation deficit played scarcely any part at all.

Some of the phenotypic and genetic parameters of East African zebu cattle and their crosses with the Indian Sahiwal zebu cattle, especially in relation to milk production, were discussed by E. B. Galukande ("The Genetics of Milk Production in East African Zebu Cattle"). The available genetic parameters suggest that up to 50 per cent of the total variation in milk yield and length of lactation period are attributable to additive genetic variation, but the rates of genetic progress due to selection have been very low—a result in agreement with what has been discovered elsewhere in the tropics. He considered that the small East African zebu animal has only about half the genetic potential of the Indian Sahiwal for milk production, and he associated the increased milk production in Sahiwal grades with an increased length of period of lactation, a shorter dry period, and a slightly longer calving interval than in the East African zebus. M. Harrison talked on "The Application of Population Genetics to the Improvement of Maize in Kenya". Pyrethrum breeding was discussed during two talks by R. B. Contant. In the first ("Present Concepts of Pyrethrum Breeding"), he considered the genetic nature of the main selection characters and some experimental and mathematical procedures for the assessment of variability in populations, heritability, and progress under selection. He then considered the content of pyrethrin in relation to complications arising from the negative correlation between flower yield and pyrethrin content, and made predictions of future progress in both. In the second paper ("Investigations on the use of *Chrysanthemum* species in the Improvement of Pyrethrum (*C. cinerariaefolium*)"), existing and desirable properties of pyrethrum were listed, and cytological investigations in regard to interspecific crossings were detailed. In this connexion, present work at Molo (Kenya), with special reference to *C. nivellei*, was described.

Malcolm J. Coe ("Primary Stages of Flowering Plant Colonization in the Nival Zone of Mount Kenya") described the disruptive distribution of this zone in relation to the peaks and glaciers of Mount Kenya. He observed that *Senecio keniophytum* is the first flowering plant to become established at the edge of retreating ice, followed by *Arabis alpina* and *Agrostis trachyphylla*. This investigation, supported by geological observations, indicated that the glaciers of Mount Kenya have undergone a period of advance in recent times.

Morphological features of a fungal pathogen of wheat were discussed by Dr. N. C. Otieno ("Ingress of *Cephalosporium gramineum* into Winter Wheat Seedlings and Subsequent Histological Relationships between the Pathogen and the Suscept"). He then described, for the first time, methods and avenues through which the pathogen enters the plant, the precise time of entry, and the subsequent course of the pathogen. The restriction of the pathogen to the vascular bundles was tentatively explained by regarding the pathogen as actually a saprophyte which can only attack the non-living tissues. What factor keeps it out of living tissues is so far unknown. Since it was first recorded in Kenya in 1940, bacterial wilt (*Pseudomonas solanacearum*) is one of the two most destructive potato diseases. It contaminates the soil, and R. A. Robinson and A. H. Ramos ("Bacterial Wilt of Potatoes in Kenya") have established that the Kenya strain is different from the more common brown rot. These authors amassed circumstantial evidence to show that the pathogen is exotic, and resistant varieties are as yet unknown.

Arts and Social Sciences

The papers under this heading will be treated more briefly, and are mentioned in this journal primarily to demonstrate the breadth of the meetings at the symposium.

The 1948 census revealed that the plateau areas of western Kenya had two main areas of population concentration. Dr. S. H. Ominde ("Some Aspects of Land and Population Problems in the Lake Districts of Western Kenya") detailed these, and then observed that the provisional figures of the 1962 census have shown that this concentration has become more marked since 1948. A detailed examination of the rate and source of economic expansion in three East African countries during the post-war period was made by D. P. Ghai ("Growth and Fluctuations of Money Incomes in East Africa: 1946–

1960"), and he derived statistical measures devised to quantify the relationship between changes in export and money incomes.

The concept of the African personality was presumed to have a social significance by Cleo Kumalo ("Toward a Sociological Approach to the Concept of the African Personality"), and he went on to raise the basic question of whether and how that reference can be discovered through the logico-experimental method of science. In his topical talk, Donald S. Rothchild ("Progress and the One-party State") concluded that the evidence for a correlation between political processes and economic progress is neither complete nor convincing. R. C. Bridges ("Are Explorers Redundant in East African History?") asserted that impressions given in Europe by explorers' exploits created a "frame of reference" within which missionaries and administrators worked, and in this way explorers' work is, indeed, a factor in the history of East Africa. Another topical talk was that given by A. K. Mayanja ("The Rule of Law in Emergent African States"), who recommended that both the formal and metalogical aspects of the rule of law need to be insured against legislative erosion.

Jonathan Silvey ("Formal and Informal Learning through the Medium of a Second Language") considered Bernstein's concept of public and formal (or individualized) language in relation to the language modes characteristic of rural and educational life in East Africa. These meetings were ended by J. Kariuki ("Poetic Works") reciting a number of his own poetic works.

The proceedings of the entire symposium are to be published. This is just one of the many decisions made at the annual general meeting and the meeting of the Executive Council. Others are the decision to hold the next symposium meeting in Nairobi next May; the appointment of several standing committees (Research and Studentships, Conferences and Liaison, Editorial and Symposium, Education, and Membership); collaboration with the Ghana Academy of Sciences in bringing to fruition the *Encyclopaedia Africana* project; decision on the principle of admitting societies operating within East Africa to institutional membership; and plans for bringing about the formal recognition of the Academy as their national academy by the East African Governments. Dr. N. C. Otieno, lecturer in botany, Royal College, Nairobi, was elected president of the Academy, Dr. J. Njoroge (plant pathologist, Scott Agricultural Laboratories, Kabete), secretary, and Mr. M. Alala (lecturer in mathematics, Royal College, Nairobi), treasurer.

THOMAS R. ODHIAMBO

THE DELHI PILLAR

THE mystery which has enveloped this quite remarkable piece of metal should be once and for all removed as a result of three papers published in the February issue of the *Journal of the National Metallurgical Laboratory of India* (5, 24; 1963). All that has been previously written is summarized and the theories propounded to explain its resistance to corrosion are collected. Despite efforts by M. K. Ghosh and by Lahiri, Banerjee and Nijhawan to support the view that there was something about the manufacture of the metal which endowed this remarkable forging with special resistance, there can be little doubt that Bardgett and Stanners's conclusions deserve acceptance.

Made by hammer-welding small balls of native iron of a fairly wide range of carbon contents, its resistance to corrosion during the 1,600 years or so of its existence is ascribed to the combined influence of a number of normal, favourable factors. Among these are included the climate and freedom from pollution of the atmosphere which exceeds Vernon's critical humidity of about 80 per cent for less than 5 per cent of the year. Secondly, to a progressively decreasing rate of attack due to the building up of a protective layer of oxide and scale during the early years of exposure.

That in the past on ceremonial occasions the pillar was anointed appears to be probable, while even to-day it is repeatedly handled. This is supported by the X-ray analysis of a minute sample of the surface coating about 5 ft. above the base which contained no iron and only quartz and chalk providing another source of protection. The authors conclude, and it is impossible to disagree with them, that "It is evident that a number of favourable factors have been acting simultaneously and the sum total of the information leads to the view that, although one may justly admire the skill and technology of the early Indian ironworkers in producing so large a monument, there is no reason for surprise at the longevity of the pillar. The composition and structure of the iron or its method of manufacture can only have contributed in a minor degree to its preservation and are in no way essential for this. The present authors, indeed, are as confident as one can be in such matters that, given the same circumstances and environment, a pillar forged from modern tonnage steel would, after 1,600 years, have been practically as preserved". Coming from men of such experience and in view of all the evidence here set out, it is impossible to disagree with this view.

The other two papers also discuss the technological aspects of ancient iron-making in India and confirm the account given in Percy's book on iron and steel of a hundred years ago. In particular, they refer in some detail to the iron beams at the Sun Temple of Konarak which show similar resistance to corrosion to the Delhi pillar despite the fact that they are situated on the sea coast. Lahiri, Banerjee and Nijhawan's insistence on the protective influence of envelopes of slag around the metal may here have exercised a decisive influence.

F. C. THOMPSON

RECOGNITION OF SEDIMENTARY ENVIRONMENTS

FOR more than a century geologists have striven to discover criteria by which the environment of deposition could be inferred from the characteristics of arenaceous rocks. Concentration on one or another aspect has changed over the years, providing a mass of data which have underlined the breadth of the problem without providing a simple solution.

Investigations of the particle size distribution of modern sediments have shown that many environments can share similar distributions, while work on the hydraulic aspects of particle transport and deposition has failed to explain the complex nature of many natural sediments. For some years there has consequently been a tendency to rely less on granulometric analyses and more on forms of bedding, such as ripple marks, laminations, and other small sedimentary structures. But here also there are hints that few, if any, of the supposedly diagnostic features are unique to any one environment, and the feeling is gaining ground that the environment in which a given sample was deposited can only be deduced reliably by considering the complete suite of associated sediments.

Some renewal of hope that at least wind-laid, water current-laid, and wave-laid sands and gravels can be differentiated by an examination of the size and shape relations of the particles in a small sample is offered by A. J. Moss ("The Physical Nature of Common Sandy and Pebbly Deposits. Part II": *American Journal of Science*, 261, 297; April, 1963). Because the stability of a particle on a bed depends largely on the effects of neighbouring particles, it is shown that there is a strong tendency for grains of similar size, shape, and density to accumulate together from a saltating traction load. The resulting population may be accompanied by a population of particles small enough to reside in its interstices, and one of particles large enough to be slid or rolled over its surface. The relative abundance of these populations, which can be recognized in modern and fossil sediments, forms the basis of interpreting the environment.

Extensions of the idea help to explain many peculiarities of natural deposits, such as the formation of heavy mineral concentrates, the abrupt changes in texture of adjacent laminæ, and the simultaneous accumulation of particles of widely differing size. They also explain the failure of granulometric analysis, as usually carried out, and provide a unifying link between the textural and structural approaches to the problem.

J. C. M. Taylor

ESTIMATION OF RUBY LASER OSCILLATION LOSS

By JOSEPH I. MASTERS

Technical Operations Research, Burlington, Massachusetts

LASER action in a pulsed system requires that during the pump cycle a population inversion be attained which is sufficient to provide enough gain per optical transit to overcome the various losses of the loaded laser enclosure. In addition to end-wall transmission losses, which are accurately known from end-reflectivity specifications or direct measurement, there are also internal oscillation losses in solid laser media caused primarily by scattering, non-resonant self-absorption, end-wall absorption and scatter, and crystal non-uniformities, none of which is directly measurable.

The two principal effects of internal losses are an increase in threshold pump power for onset of oscillation over predicted values and a decrease in output energy above threshold. The latter is dramatically indicated by the ruby laser output shown in Fig. 1 (ref. 1), where the Q or internal radiation lifetime of the laser enclosure is made greater by increasing end reflectivity r from a low value while the pump energy pulse remains unchanged. From energy considerations, we would expect to see no decrease in integrated output energy under these conditions in the absence of internal loss mechanisms. Therefore, the observed reduction in output is evidence of significant loss per transit, enhanced in this example by the effective increase in the number of transits as r is increased.

It was found practical to examine internal losses by investigating conditions at threshold, since this specialization eliminates from the problem well-known uncertainties in measurement and interpretation of output power. The estimate of the degree of internal loss is accomplished by comparison of experimental results with theoretical curves. From the point of view of a mathematical model, threshold is defined by use of a step function optical pump input to a population rate problem that is based on an idealized ruby energy level system. Threshold pump power, then, is a step function in time of photon flux density or of pump transition probability sufficient to produce a steady-state population inversion ΔN that satisfies an oscillation condition of the form $\Delta N\, l\, \sigma = \ln r$, where σ is the cross-section for the laser transition and l is the optical path-length between reflexions characterized by r. Similar mathematics with only slight variation in assumptions have appeared in detail previously[2-5]. Therefore, only the particular assumptions and solution employed here are stated.

A four-level ruby system is assumed in which atoms excited by pump photons from the ground-state to absorption bands rapidly decay non-radiatively to the metastable R_2 and R_1 levels ($\nu_{R_1R_2} = 29$ cm^{-1}), which, in turn, rapidly thermalize to a Boltzmann distribution. These two processes are so fast compared with the reciprocal of the pump transition probability or the R level lifetime that a pump photon absorption is assumed to excite a ground-state chromium atom directly to one of the R levels. For the low-temperature limit of interest in this article, ~150° C, the Boltzmann distribution of the closely spaced ground-state levels is taken as equal. Since small ΔN threshold conditions prevail, the only laser transition considered is from the level R_1 to the ground-state, and the only loss assumed from the excited state prior to laser action is by unamplified spontaneous emission. The variations of the laser transition line width $\Delta\lambda$ with temperature and R level Boltzmann distribution are the only temperature dependencies considered. In addition, we make the assumption that the laser medium is optically thin, or that the pump photon flux is uniform in the sample. These assumptions yield the following solution for ruby threshold power versus reflectivity and temperature T:

$$P_{\text{rel}} = A\,\{[1 + \exp(42/T)] - 2\ln r\}\,/(2A + 2\ln r) \qquad (1)$$

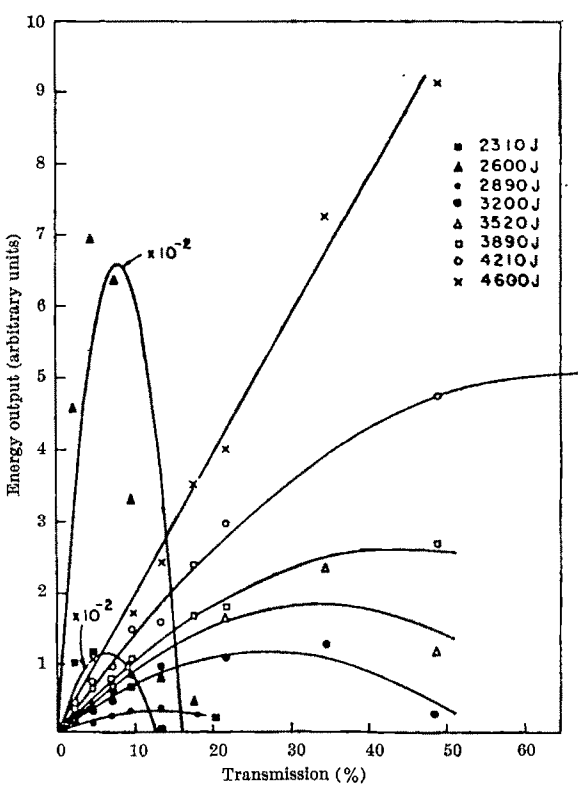

Fig. 1. Ruby laser output for various fixed values of input energy

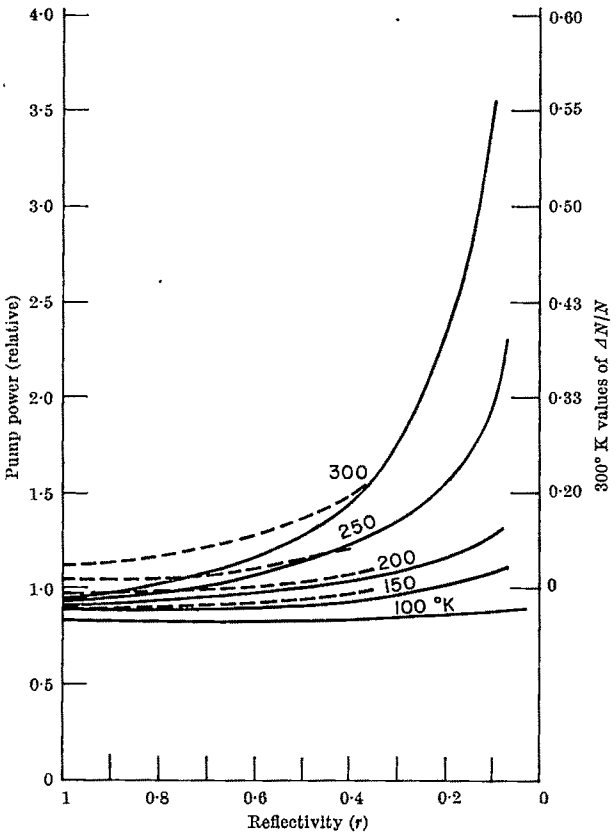

Fig. 2. Ruby laser threshold conditions. $l = 10$ cm

where $A = N\sigma\ l$ and $\sigma(T) = \sigma(300°)\ \Delta\lambda\ (300°)/\Delta\lambda(T)$. For the room temperature value of the laser transition cross-section, the value $\sigma(300°\ \mathrm{K}) = 2{\cdot}5 \times 10^{-20}$ cm^2 is used[2]. Values of $\Delta\lambda(T)$ are taken from Schawlow[6]. For comparison with laboratory data, values of constant pump power are given on a relative basis and are normalized so that $P_{rel} = 1$ is the pump power required for inversion ($\pm\ \Delta N = 0$) in a three-level system. Theoretical curves, however, will drop below unity for large r and low T because of the effect of the Boltzmann distribution of the R levels on the population of the R_1 laser transition level. As an example, equation (1) is plotted in Fig. 2 as a family of solid curves for various temperatures for the case $l = 10$ cm. Inversion values for 300° K only are given on the right scale.

Laboratory results were obtained using ruby rods of 90° orientation and ~ 0·05 per cent Cr^{+++} doping ($N \cong 1{\cdot}6 \times 10^{19}$ ions-cm^{-3}) that were nearly totally reflecting on one end. Variation of reflectivity at the output end was accomplished by using mirrors of several reflectivities employed as an external opposing reflector of the laser enclosure. External reflector displacement, however, was small enough to preclude far field effects[7]. A conventional helical xenon flashlamp was used for pumping. Because of near total reflexion at one end of the laser rod, the value of the transit distance l within the active medium between mirrors of reflectivity r is effectively twice the physical rod-length.

In actual practice, experimental threshold results versus reflectivity and temperature are not in a form suitable for direct comparison with theoretical curves. The comparison is made possible by the use of two first-order approximations. The first approximation accounts for the fact that only threshold electrical energy rather than threshold radiant pump power is measurable, and that the pump energy is not delivered at a constant rate, as assumed theoretically, but usually follows the discharge of a large inductive storage capacitance C. The second approximation must establish a criterion for normalization of experimental pump data, since values of this quantity are, at best, relative.

The pump power approximation is made by relating electrical stored energy E and average lamp power P and by assuming further that effective pump photon flux is proportional to P. We note from xenon flashlamp data that lamp resistance R is nearly constant, at least for the first half of the flash, and that the voltage decay is approximately exponential. Thus:

$$\bar{P}_\theta = \frac{1}{R\theta} \int_0^\theta \left(V_\theta e^{-t/RC} \right)^2 dt$$

where θ is the time to reach threshold as measured from the beginning of the pump pulse, or, when θ is used as a subscript, it denotes a threshold quantity. The integration yields:

$$\bar{P}_\theta = E_\theta\ (1 - e^{-2\theta/RC})\ /\theta = E_\theta F(\theta)$$

where $F(\theta)$ is a slowly varying function that decreases from the value $2/RC$ with increasing θ. We are particularly concerned with threshold data at various temperatures for values of r approaching unity, and under these conditions θ itself was found to vary only slightly. We assume, therefore, that $F(\theta)$ is essentially constant or that threshold electrical energy values and average pump power are proportional.

The second approximation, that of normalization, is handled by taking advantage of a property of the physical system apparent from the 100° K or 150° K theoretical curves shown in Fig. 2. Here we see that at low temperatures, when the gain is great, the pump power for threshold is only slightly larger than the pump power for attaining inversion even if losses are very large; that is, at 150° K, if r is as small as 0·3, less than 10 per cent increase in P_{rel} is required to attain threshold. The experimental value of E_θ for 150° K and $r \to 1$ for a given sample was thus co-plotted with some confidence on the theoretical curves for this temperature, and all other experimental points were normalized by dividing their E_θ values by $E_\theta\ (150°)/P_{rel}\ (150°)$. The experimental curves in Fig. 2 (dashed lines) result from this procedure.

An enhanced vertical spread of the data curves as $r \to 1$ results from various internal propagation losses. Evaluation of the internal loss factor is accomplished by generalizing the threshold condition in the form $\Delta N\, l\sigma = \ln r_{eff}$. In this notation $r_{eff} = r$ for the idealized model (solid-line curves), whereas $r_{eff} = rr'$ for real samples in which $1 - r'$ accounts for internal losses, that is, all losses other than transmission loss. The desired loss factor $1 - r'$ for a laser rod sample being examined may now be obtained simply by fitting the vertical spread in the experimental temperature curves at $r = 1$, for which $r_{eff} = r'$, with an equal spread in the solid theoretical curves. Thus the estimated loss factor is unity minus the abscissa value corresponding to the matching vertical spread in the solid-line curves.

By following this procedure, the data taken from a 2 in. × 0·25 in. ruby rod (Fig. 2) indicate an estimated loss factor of 35–40 per cent for a transit of twice the rod's length, which is typical of the best available ruby samples of this size that were tested.

I thank John H. Ward and Howard R. Huff for assistance and Sylvia W. Masters for performing calculations. This work was supported by the U.S. Air Force Cambridge Research Laboratory under Contract No. *A F*19(628)–405.

JOULE HEATING OF THE IONOSPHERE OVER HALLEY BAY

By K. D. COLE

Antarctic Division, Department of External Affairs, Melbourne

In earlier communications I reported investigations of joule dissipation in the ionosphere[1–3]. Some spot estimates of the heating were given previously. It is the purpose of this communication to derive a distribution (with magnetic disturbance) of such heating in the ionosphere over Halley Bay (75·5° S., 26·6° W. geographic) using information provided by the Royal Society International Geophysical Year Antarctic Expedition[4] to that place. An important correction to one source of information previously used by me in connexion with joule heating is also noted.

The Royal Society's expedition to Halley Bay made simultaneously observations of the geomagnetic field and soundings of the ionosphere with an ionosonde. These two sets of observations together provide estimates of the joule dissipation in the ionosphere which is given by the formula:

$$Q_j = j^2/\sigma_3 \qquad (1)$$

where j = ionospheric current density, σ_3 = Cowling conductivity[5].

Consider a polar situation in which the geomagnetic field is approximately vertical; and electro-static field is applied so that the geomagnetic field lines are equipotentials, and the ionosphere is assumed at rest. The heating due to an ion-electron pair and the current per ion-electron pair are distributed approximately as in Fig. 1. The peak in heating below 100 km is unimportant for changes of atmospheric structure because of the high density of atmosphere there. The peak at 150 km, however, has significant consequences. For present purposes it is assumed that the electron density is uniform with height. Two extreme models are investigated to place bounds to joule heating as a function of magnetic disturbance. Model A assumes that current flows in one direction in an infinite plane slab with a height distribution as in Fig. 1. Model B assumes that current flows above the observatory in one direction in a jet 100 km wide and distributed in height as in Fig. 1. In both models it is assumed that the value of the critical frequency f_c of sporadic E ionization can be used to define the electron density in the current region by:

$$n = mf_c^2/4\pi e^2$$

where m is the electron mass and e its charge.

If two-thirds[6] of the disturbance (ΔH) of the horizontal component of the geomagnetic field is due to ionospheric current then model A gives (in E.M.U.):

$$\left.\begin{aligned} j_{\text{av.}} &\approx 2 \times 10^{-8}\ \Delta H \\ \text{and model } B: \quad j_{\text{av.}} &\approx 5 \times 10^{-8}\ \Delta H \end{aligned}\right\} \qquad (2)$$

At the altitude where the heating peaks (about 150 km) $\sigma^3 \approx 2\sigma_1 \approx 3 \times 10^{-20}\ n$ (see model h of ref. 7) and $j \approx j_{\text{av.}}$ It should be noted in passing that these estimates of conductivity depend finally on collision cross-sections of low energy ions and electrons with neutral particles and so remain uncertain perhaps by a factor 2.

Thus, upper and lower limits to peak joule heating at 150 km altitude are suggested by the following equations:

$$\left.\begin{aligned} \text{Model } A: Q_j &\approx 10^{-10}\ \frac{(\Delta H)^2}{f_c^2}\ \text{ergs cm}^{-3}\ \text{sec}^{-1} \\ \text{Model } B: Q_j &\approx 6 \times 10^{-10}\ \frac{(\Delta H)^2}{f_c^2}\ \text{ergs cm}^{-3}\ \text{sec}^{-1} \end{aligned}\right\} \qquad (3)$$

where ΔH is now in gammas ($1\gamma = 10^{-5}$ gauss) and f_c is in Mc/s.

In their Fig. 27, Bellchambers *et al.*[8] show the distribution at Halley Bay of f_c with magnetic disturbance as measured by the magnetic disturbance index Q (not to be confused with Q_j). Q is a quarter-hourly measure of disturbance based on the same principles as the magnetic K index. It therefore does not strictly represent steady-state disturbance; however, it is here considered to give the best available representative estimate of the steady (or d.c.) disturbance at any one time. The bulk of their observations relate to magnetic disturbance in the range 10–500γ. Elsewhere[9] it was shown that at a station of similar distance from the auroral zone as Halley Bay (namely, Macquarie Island) magnetic bays of amplitude $> 200\gamma$ had durations generally > 50 min. Such bays can therefore be considered as virtually a d.c. phenomenon.

Using Fig. 27 of Bellchambers *et al.* and equations 3, a distribution of Q_j versus ΔH is delineated (Table 1). This suggests upper and lower limits for Q_j.

Table 1

ΔH (γ)	50	100	200	500	1,000
		Q_j (ergs cm^{-3} sec^{-1})			
Model A	6×10^{-8}	7×10^{-8}	3×10^{-7}	10^{-6}	3×10^{-6}
Model B	3×10^{-7}	4×10^{-7}	2×10^{-6}	6×10^{-6}	2×10^{-5}

It seems that only *in situ* simultaneous determinations of j and n can resolve the heating to better than the present estimates. The estimates given here confirm those obtained earlier[2], except for one previous estimate which is corrected below.

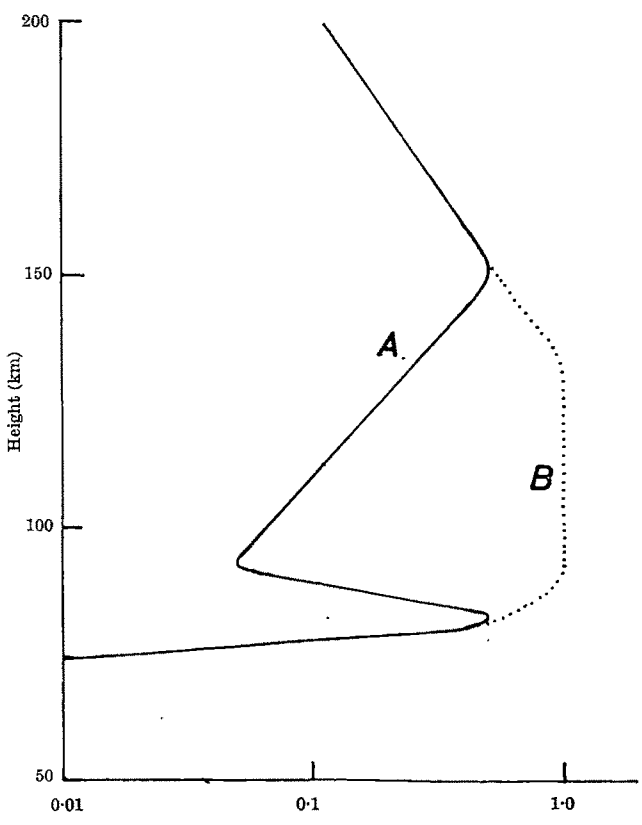

Fig. 1. Schematic representation of the distribution of: (A) Q_j per ion-electron pair (proportional to σ_3/n; (B) j per ion-electron pair (proportional to $(\sigma_1\ \sigma_2)^{1/2}/n$ under conditions in text. (σ_1, Pedersen conductivity)

Geomagnetic observations at Halley Bay during the same period are reported by McDowell and Blackie[11]. Their Fig. 32 shows that on the five most disturbed days of the months the disturbance was 200γ for about one-quarter of the time. The heating implied thereby could have important implications for the local ionosphere, such as modification of the scale height[2], changes of temperatures[2,10] and creation of winds[2]. It is suggested here that the observed increase of the heights of the tops of auroral rays at sunspot maximum (ref. 12, Fig. 76) is explainable by the bulging of auroral zone atmosphere due to joule heating.

The opportunity is now taken to correct an estimate of joule heating due to average *DS* currents in the ionosphere[1-3]. The intensity of these currents which I used had been given[13] as $1{\cdot}5 \times 10^5$ A between flow lines (about 1 degree apart near the auroral zone). It has since been pointed out[14] that this quantity was misprinted and should have been $1{\cdot}5 \times 10^4$ A. On the model adopted here this would cause a ΔH of about 100γ, and therefore a Q_J (*DS*) value in the range 7×10^{-8}–4×10^{-7} ergs cm^{-3} sec^{-1}.

Several mechanisms have been suggested for the apparent abnormal heating of the ionosphere during magnetic disturbance. First, corpuscular bombardment by energetic charged particles has been considered in various places. The observation of McIlwain[15] suggest that electrons in the energy range 1–100 keV are absorbed principally below 120 km altitude. *Bremstrahlung* from these electrons presumably is absorbed principally at lower heights. The energy flux of these electrons may be[15] commonly of order 20 ergs cm^{-3} sec^{-1} and rarely 2,000 ergs cm^{-3} sec^{-1}. Supposing their energy is absorbed in a 50-km thickness of atmosphere, then commonly their energy input into the atmosphere may have an upper limit of about 4×10^{-6} ergs cm^{-3} sec^{-1}. This energy absorbed by neutral particles would appear to have little effect on their temperature because of the high density of atmosphere below 120 km.

Secondly, Dessler[16] considered the damping of hydromagnetic waves in the ionosphere and came to the conclusion that waves of frequency about 1 c/s were most important in this regard and deduced a peak heating rate of about 3×10^{-9} ergs cm^{-3} sec^{-1} at an altitude of about 175 km. Francis and Karplus[17] subsequently examined the dissipation of hydromagnetic waves in the frequency range $\omega = 1 - 25$, and fully confirmed Dessler's estimates of heat input. Akasofu[18], however, found that the rise in atmospheric temperature due to the likely naturally occurring hydromagnetic waves in this frequency range was not greater than 5 degrees.

Thirdly, I[1-3] have investigated the joule dissipation of the quasi-steady electric currents which flow in the ionosphere to cause the basic geomagnetic disturbance variations, for example, the auroral electro-jets and the associated *DS* current system. The heat input due to this d.c. heating peaks at an altitude of about 150 km and is capable of causing significant changes in the temperature of gases there[1-3,10]. Table 1 shows estimates of such heating. Heat input at this height and of this magnitude is favourable for the production of significant changes in structure of the atmosphere at and above 150 km. It is suggested that the joule dissipation of these quasi-steady ionospheric currents is the most effective of the three heating methods mentioned here for the production of such atmospheric changes.

PETROFABRIC ANALYSIS OF QUARTZ USING THE POINT-COUNTER

By A. G. MILNES

Mineralogisch-Petrographisches Institut der Universität, Bernoullianum, Basel

AT the beginning of the century, people were toying with the idea of determining the orientation of quartz c-axis in a rock using the gypsum plate and statistical methods[1-3]. After the publication of Berek's book[4], the use of the universal stage for petrofabric determinations was realized. The gypsum plate method has since been completely neglected; quantitative estimation by this method was extremely inaccurate and had no time advantage over the universal stage.

The method described here was developed independently of the foregoing methods in response to a need to investigate systematically both the compositional variations and the fabric variations throughout a large gneiss body (the Antigorio nappe, the lowermost of the Alpine nappes). Owing to the length of time needed to analyse a single thin-section with the universal stage (measuring, plotting and contouring), systematic investigations cannot be carried out by this method. Using the point-counter and gypsum plate, the quartz orientation can be estimated at the same time as the mineral composition, and without any increase in the time required to estimate the mineral composition alone. Modal analysis of a stained thin-section of a normal gneiss, including the procedure for quartz about to be described, takes 0·5–0·75 h.

The procedure is exactly as for a normal estimation of mineral composition, with the following modifications:

(*a*) The thin-section must be stained (plagioclase—red, alkali felspar—yellow, quartz—uncoloured[5]); the gypsum plate is kept in continually and all minerals except quartz are counted with uncrossed nicols.

(*b*) The thin-section is always cut perpendicular to the foliation and the trace of the foliation is orientated always parallel to the same vibration direction of the gypsum plate (I place the foliation of every thin-section parallel to α (see Fig. 1)).

(*c*) Quartz is counted with crossed nicols on three separate keys, one for when the quartz is definitely blue, one for when definitely yellow and one for when red (that is, any shade of colour which cannot be called definitely blue or yellow), the numbers obtained being *B*, *Y* and *R* respectively.

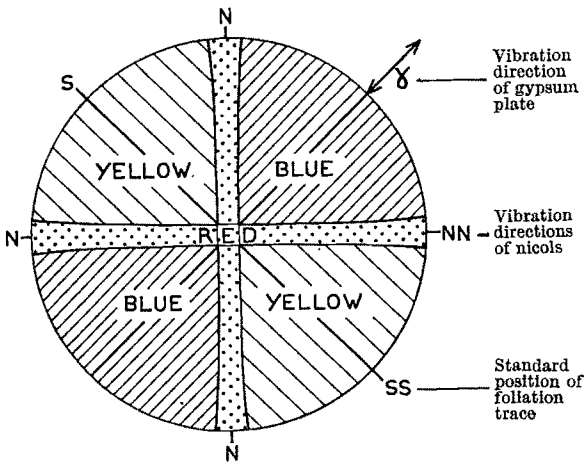

Fig. 1

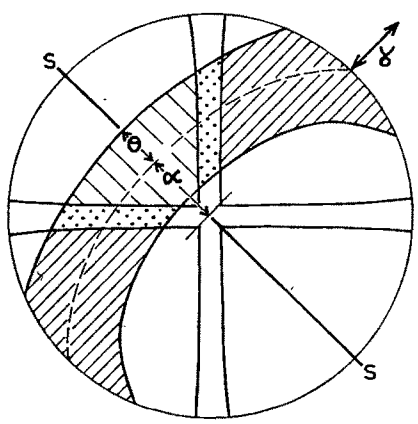

Fig. 2

(*d*) The BY-ratio and R-ratio are calculated and plotted as described below.

Determination of the red cross. Let us consider a thin-section of a quartz-rich sediment, for example, rounded quartz grains in a calcite matrix, the quartz having been subjected to no systematic movements with respect to the *c*-axis. If we measure the *c*-axes using the universal stage, and plot the measurements in the usual way on a Schmidt net, the result will be a homogeneous even-density pole distribution, corresponding to random axis orientation. Suppose also that we note the colour of each grain we measure when the gypsum plate is inserted and the thin-section is placed in one previously decided position. The colour scheme of the resulting diagram will be as in Fig. 1.

If we measured enough axes, we would be able to draw a line between the red and blue and yellow areas of the diagram and these lines would lie approximately along small circles, the four limbs of the red cross being symmetrical and of equal angular width.

Now let us take the same thin-section and, counting the quartz on three keys as above, use the point-counter to obtain the numbers B, Y and R. What is the relation between these? We would obviously expect that one relation should be: $B = Y$. Also, the relation between R and the others must be a measure of the angular width of the limbs of the red cross. Recognition of the truth of this last statement is the key to this method, since the angular width of the red cross is a constant, independent of the pattern of the quartz orientation. It should be noted that the numbers B, Y and R are proportional to the areas of the blue, yellow and red regions of the diagram we prepared using the universal stage.

In order to illuminate the significance of the relations between these three numbers, when they are obtained from actual thin-sections, I have worked out a number of idealized quartz orientation patterns. The first step is to determine the angular width of the red cross using thin-sections in which it is reasonably certain that there is random orientation of the quartz *c*-axes. I chose sections of sandstones with the quartz grains more or less separated by calcitic or chloritic matrix. Some sections were repeated with different positions of the stage. The following ratios and standard deviations were obtained, using the point-counter to determine the numbers B, Y and R as above.

$$BY\text{-ratio} = 1{\cdot}0 + 0{\cdot}1$$
$$R\text{-ratio} = 7{\cdot}7 \pm 0{\cdot}7$$

the ratios being defined as follows:

$$BY\text{-ratio} = B/Y \text{ or } Y/B \text{ (always greater than 1)}$$
$$R\text{-ratio} = (B + Y + R)/R$$

From these ratios the angular width of the red cross was obtained by a method of trial and error—crosses of varying width were drawn over a Schmidt net and the diagram covered with points placed at the intersections of an evenly spaced rectangular grid (20 cm net, axes of grid not parallel to axes of cross, lines of grid 0·5 cm apart). Hence the area of a given cross could be determined by counting the points within its boundaries, as could the total area of the circle. By this method it was found that an angular width of 8° gave:

$$R\text{-ratio} = \frac{\text{total area } (B + Y + R)}{\text{area of red cross } (R)} = 7{\cdot}54$$

Hence it was determined that I could not distinguish between blue and yellow if a quartz *c*-axis lay with an angle of less than 4° from two vertical planes representing the vibration directions of the upper and lower nicols. The cross is drawn with this angular width in Figs. 1 and 2.

Now we can go on to consider what ratios we are likely to obtain from certain simple idealized orientation patterns.

(1) *Girdle perpendicular to foliation.* This is a common case in nature; sometimes the girdle will be around a linear structure, but often no lineation will be observable in the hand-specimen. When no lineation is available, the thin-section will be cut at some unknown angle with respect to the plane of the girdle, the thin-section only being orientated with respect to the foliation. The angle between the plane of the girdle and the pole of the thin-section is designated α (Fig. 2).

In order to treat the shape of the girdle we must make the following simplifications: (*a*) the girdle is parallel-sided, that is, with small circle boundaries; (*b*) the pole distribution within the girdle is homogeneous. Hence we can designate the angular half-width of such a girdle, θ (Fig. 2), a quantity which is a measure of the intensity of development of the girdle.

From the second simplification, we see that the areas of blue, yellow and red of the girdle, as in Fig. 2, are proportional to the number of grains falling in each area (as would be determined using the point-counter). Different values of α and θ will produce different pairs of BY- and R-ratios.

The areas of such girdles have been calculated systematically (by the same method as described above for determining the width of the red cross), that is, values of θ were taken 10° apart from 0° to 90°, and for each θ the areas of blue, yellow and red (=numbers B, Y and R) calculated for α = 0°, 30°, 60°, 90°. From these areas the BY- and R-ratios were worked out and plotted as in the lower half of Fig. 3. Each point lies at the intersection of two lines, an α-line (thick dashed) and a θ-line (thin continuous).

In order to test these curves with a real thin-section, a hand-specimen was chosen which was suspected to show a

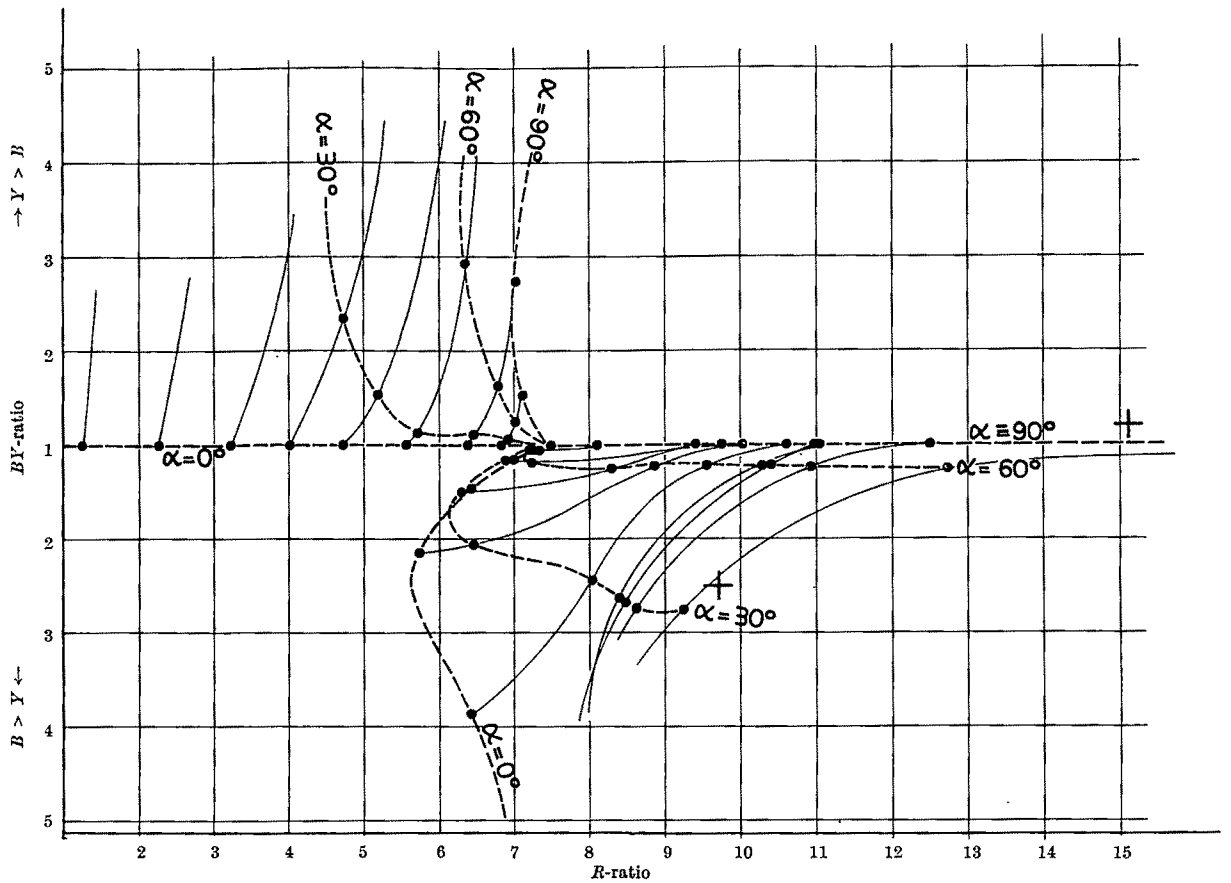

Fig. 3. *BY*–*R*-diagram of ideal girdle (lower half) and ideal pole-maximum (upper half)
α-line, thick dashed; θ-line, thin continuous. θ = 90° is random orientation and gives *R*-ratio = 7·5; θ-lines spaced at 10° intervals decreasing outwards from this point. + + = thin-sections mentioned in text

strong girdle orientation. This was an intensely rodded quartzite[6], and two sections were cut, one perpendicular, the other oblique (27°) to the rodding. These gave the following results (see Fig. 3):

perpendicular : *BY*-ratio = 1·3 (*Y* greater than B)
R-ratio = 15·1
oblique: *BY*-ratio = 2·5 (*B* greater than Y)
R-ratio = 9·7

When we remember that both the simplifications on which the curves are based are completely unlikely to occur in nature, these points fit surprisingly well:

(*a*) The line joining the two points is approximately parallel to the nearest θ-lines of the ideal and in a position not very different from that of the most 'intense' (θ → 0°) of these lines.

(*b*) The perpendicular section lies close to the 90° α-line and the oblique section lies close to the 30° α-line.

These points fit so well with the ideally expected values that we can now say with certainty that we are dealing with a girdle about the rodding axis and that this girdle must be strongly developed. The total time required for counting the sections (1,000 quartz grains in each) was 1·5 h.

In the case of simple orientation patterns (see also later cases), this method of counting two or more sections of the same hand-specimen gives a fair idea of the pattern-type and intensity of orientation ; it becomes 'semi-three-dimensional'. I do not believe, however, that it has any practical use, since for more complex patterns there are no ideal curves for comparison and as soon as more than four thin-sections have to be counted for no other reason than an investigation of the quartz fabric, then the universal stage is as quick and much more definitive.

These objections are completely reversed however if we are carrying out a systematic study of a large gneiss mass. This involves an investigation of compositional variations but up to now the fabric could not be treated systematically—the time required to measure hundreds of thin-sections using the universal stage is completely prohibitive. Now, however, with each modal analysis, a *BY*- and an *R*-ratio for the quartz is obtained without increasing the time required for each thin-section.

Let us take an imaginary example to find out what we would expect from such an investigation. We have a gneiss mass which has been worked on with universal stage methods and found to give a good girdle perpendicular to the foliation (as above) in all thin-sections measured (probably not more than 10, and 200 grains per section). During systematic modal analysis we have obtained very many pairs of *BY*- and *R*-ratios (for example, 110 in the example to be cited later, 300–1,000 grains per section) and plotted them on the same diagram as the ideal curves. Suppose also that the gneiss has only rarely a lineation; most thin-sections are cut randomly but always perpendicular to the foliation. We would expect the points to show the following features:

(*a*) α varies from thin-section to thin-section, therefore the points will be concentrated in a zone parallel to the corresponding θ-line and will be equally distributed along the length of the zone. An additional requirement is that, when a lineation is present and if the lineation and the quartz orientation are the results of the same movements, sections perpendicular to the lineation should fall near the 90° α-line, sections parallel near the 0° α-line and oblique sections intermediate.

(*b*) If θ (= intensity of development of the girdle) was completely constant throughout the gneiss mass, this zone would be very narrow and by comparison with the

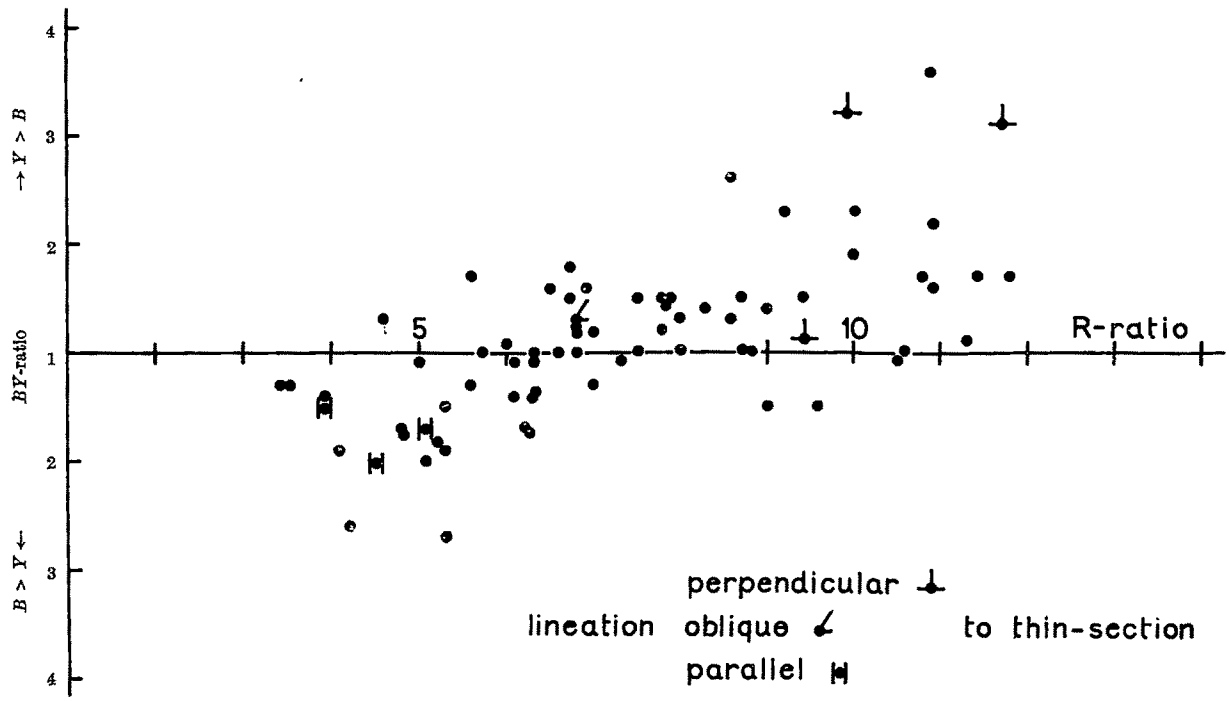

Fig. 4. *BY–R*-diagram of Antigorio gneiss

ideal curves would give a value of θ, a semi-quantitative measure of the intensity of orientation.

(*c*) If θ was not constant, the zone would tend to be broad and irregular, but still approximately parallel to the θ-lines of the ideal curves and still in the form of one elongate maximum. We then have the possibility of determining whether the less well-orientated gneisses are confined to a definite tectonic region (by plotting the points with different symbols representing different tectonic positions) or even whether the intensity of orientation depends on mineralogical or microscopic textural features (different symbols according to mineralogical or textural criteria). This will be illustrated by the example later.

(2) *Single pole-maximum in plane of foliation* (*a*-maximum).

Another common case in nature, the axis of the maximum often parallel to the direction of transport. This has been treated in exactly the same way as the girdle (upper part of Fig. 3). In this case, α = angle between axis of maximum and pole of thin-section, and θ = angular radius of a perfectly circular maximum with homogeneous pole distribution within its boundary.

The same discussion applies here also. The first obvious difference between pole-maximum and girdle is:

pole-maximum — *Y* greater than *B*
girdle — *B* greater than *Y*.

Another difference is that for a pole-maximum, *R*-ratio tends to be smaller than 7·5, while for a girdle the tendency is to be larger.

(3) *Single pole-maximum perpendicular to foliation* (*c*-maximum).

Again a common natural pattern and easily distinguishable from the above two, since however the section is cut (as long as it is perpendicular to the foliation), the maximum will have the same position in the thin-section. Hence there is no equivalent of α here and the *BY–R*-ratio diagram from a gneiss mass with such a fabric throughout must give a single non-elongate maximum, the position of which represents θ (intensity of orientation). This non-elongate maximum must lie on a line which is the same shape and in the same position as the 90° α-line of the second case, but lying on the *B* > *Y* side of the diagram.

(4) *Girdle in plane of foliation.* An unusual case in nature, the argument being similar to case 3.

Fabric analysis of the Antigorio gneiss using this method. Fig. 4 shows the results of modal analysis of 110 thin-sections of 'normal' Antigorio gneiss (that is, not including many analyses of veins, shear zones, local facies, etc.).

The points fall in a broad but definitely elongate zone which does not coincide with the ideal curves, that is, we are here dealing with a more complex pattern. That the pattern, whatever its exact shape, is constant throughout the gneiss mass, and that the *BY–R*-diagram represents one pattern and not, for example, two superimposed patterns is proved in the following way:

(*a*) Contouring the points would produce one continuous maximum.

(*b*) In most cases the gneiss is unlineated; but when a lineation was present, the orientation of the lineation with respect to the thin-section has been also noted on the *BY–R*-diagram. It is immediately obvious that thin-sections cut perpendicular to the lineation occur at one extreme end of the zone, thin-sections cut parallel at the other, and oblique sections somewhere between. By analogy, from the discussion of ideal cases above, we see that the long axis of the zone represents 'α', the orientation of the pattern with respect to the thin-section. Such a relationship can only be understood if the lineation and the quartz fabric are the results of the same deformation.

(*c*) The width of the zone must therefore represent the spread of the intensity of orientation (see above), that is, the variation of θ. The points were plotted with different symbols denoting different tectonic positions, and with different symbols according to mineralogical and textural features of the quartz in thin-section. There was never any tendency towards segregation of these symbols on the *BY–R*-diagram, further proof that one particular quartz orientation pattern is responsible and is a typical feature of this gneiss.

A few thin-sections of very strongly lineated gneisses give a second, exactly similar zone, parallel to and below the one illustrated here, outside the range of Fig. 4. Since, presumably, the strongly lineated gneisses show a

more intense quartz orientation than the normal, unlineated varieties, the displacement of the zone must represent this difference in intensity of orientation (that is, two different values of θ giving two parallel zones). The number of these sections is, however, still too small to give a good statistical basis.

From a general consideration of more complex quartz patterns, I find that the simplest pattern which could produce the distribution of Fig. 4 is an incomplete girdle (around the lineation when present), the 'gap' in the girdle being situated around *c* (the pole of the foliation). The exact shape, however, is unimportant since it is defined by the point distribution of the *BY–R*-diagram and the patterns from different gneiss masses can be compared on this basis alone. This method gives a statistical idea of the quartz fabric throughout a large rock mass, enabling one to see through the local variations towards the regional picture.

I thank Profs. P. Bearth and E. Wenk and Dr. V. Trommsdorf, of Basle, for stimulating criticism and useful suggestions, and acknowledge the receipt of a NATO studentship which made this work possible.

GEOCHRONOLOGICAL INVESTIGATIONS ON ROCKS FROM NORTH WALES

By F. J. FITCH
Department of Geology, Birkbeck College, University of London
AND
Dr. J. A. MILLER and M. Y. MENEISY
Department of Geodesy and Geophysics, University of Cambridge

AN extensive programme of age measurements on rocks from North Wales using the potassium–argon method is being carried out at present in the laboratory of the Department of Geodesy and Geophysics, University of Cambridge. The salient features of the age-pattern emerging from this work are revealed by the preliminary results listed in Table 1. Argon volumes were estimated using the isotope dilution technique and the potassium oxide content of the samples measured by flame photometry. The geological interpretation is largely due to Fitch, while the geochronological work has been done by Miller and Meneisy. Full detailed results on a more comprehensive range of North Welsh rocks will be published later.

The proved or inferred geological ages of the rocks forming this preliminary sample range from the pre-Cambrian to the Tertiary. The pre-Cambrian (Monian) age relationships of the Coedana and Sarn granites, and of the Gabbro–Serpentine Complex of Rhoscolyn, have been discussed by Greenly[1], Matley[2], and Shackleton[3,4]. The Twt Hill granite is referred to as of younger pre-Cambrian (Arvonian) age by Greenly[5]; the Uriconian volcanics, although definitely pre-Cambrian, are not thought to correspond to the Arvonian or Monian because of their inferred relationship to the Longmyndian[6,7]. Stanner rocks, once thought to be intrusive into the Ludlovian, are now regarded by Holgate and Hallowes[8] as a slice of Uriconian basement brought up in the Church Stretton fault zone. The Ordovician volcanic rocks Carreg y Defaid have been dated on palæontological evidence as Caradocian by Matley[9]. The extensive basic sill and dyke complex of North Wales has been variously interpreted; but it is now accepted that the majority of these minor intrusions were emplaced in a late phase of the main end-Silurian Caledonian movements, as is maintained by Shackleton[7,10]. Both the Llanbedrog and Penmaenmawr plutons are examples of an extensive suite of small stocks, plutons and domes found in North Wales. They have been regarded as Ordovician in the past[11], but the majority are now known to be late-Caledonian[10,12]. The rare alkaline basic dykes of Anglesey and the mainland are thought to be Tertiary by Greenly[1,13].

Potassium–argon results obtained from this varied suite of igneous rocks can be discussed under the five age-groups into which they fall.

Early Tertiary Ages. The analcite-bearing olivine–dolerite dykes (Crinanites) at Porth Dafarch on Anglesey and near Ogwen Cottage in Snowdonia gave total rock potassium–argon ages of 73 ± 17 and 86 ± 13 million years respectively. These rocks have long been regarded as Tertiary on petrographic grounds, and this is now confirmed: the actual period of intrusion being most probably the Palæocene. An anomalous age obtained from the Rhoscolyn Gabbro–Serpentine Complex, intruded into the New Harbour Beds on Holy Island, Anglesey, which is certainly pre-Cambrian, can only be explained by postulating the proximity of the mass to Tertiary magmatism. Further field investigation is required before this anomaly can be satisfactorily understood.

Variscan Ages. Moorbath[14] has shown that Variscan mineralization is widespread in North Wales. This mineralization is associated with a fault complex which can be readily appreciated where Carboniferous rocks are present but may be confused with Caledonian faulting and mineralization in the older core of North Wales. Basic sills of tholeiitic dolerite intruded in the later phases of the Caledonian orogeny are commonly found in the folded Ordovician rocks of North Wales. These sills are related to a north-west–south-west trending dyke swarm. Two of these basic rocks, the Holyhead Dyke on Anglesey, and the Llandegai sill near Bangor, gave true Caledonian ages. Four other 'Caledonian' basic sills sampled, those at Nant, and near Llanwrst, on Tal-y-fan, near Ro Wen, at Ty-Ruttan, near Sarn, and at the Pant Quarry, Llanwrst, gave the apparently Variscan ages of 288 ± 19, 278 ± 23, 264 ± 17 and 245 ± 18 million years respectively. The view that the ages obtained are due to partial or complete argon loss consequent on the effects of nearby Variscan mineralization and movement is strengthened by the closely comparable results obtained from the demonstrably Caradocian acid volcanic rocks at Carreg y Defaid near Pwllheli. From this locality a rhyolitic vent rock and a welded eutaxitic ignimbrite gave ages of 272 ± 13 and 279 ± 13 million years respectively. All these rocks in which excessive loss of argon is suspected show some signs of hydrothermal alteration (kaolinization, silicification, chloritization, etc.) in thin section. The basic sills from the Conway Valley are geographically close to known Variscan ore bodies (for example, Trecastell Mine and Parc Mine). The Pant Quarry rock, which gives a very low result, is extremely brecciated and subject to deep

recent weathering. No proved Variscan mineralization is known in the Lleyn; but it would appear that much of the mineralization previously regarded as Caledonian (for example, south of Abersoch at Llanfaelrhys) must in fact be Variscan.

Intermediate Caledonian/Variscan Ages. Three of the granite masses of Western Caernarvonshire, the Llanbedrog granophyre, the Sarn Adamellite and the Twt Hill granite gave the intermediate ages of 312 ± 14, 317 ± 15 and 355 ± 16 million years respectively, from samples in which potash feldspar was the main potassium-bearing mineral. The Llanbedrog granophyre is a post-tectonic Caledonian pluton and the age obtained must reflect partial argon loss in addition to that normally lost from feldspars, due to Variscan movements and mineralization. The Sarn Ademellite and the Twt Hill granite are both pre-Cambrian in age, the Twt Hill mass being the younger of the two. Both show brecciation, and shearing of Caledonian age would be expected to give Caledonian ages on analysis by the potassium–argon method. The low value obtained from Sarn is comparable to that obtained from Llanbedrog and may be attributed to mild hydrothermal alteration of Variscan age. The smaller loss of argon suffered by the Twt Hill rock is probably related to the proximity of the Variscan Dinorwic fault rather than to the passage of hydrothermal solutions.

Caledonian Ages. All but one of the remaining rocks listed in Table 1 gave Caledonian ages only slightly modified by later events. The Penmaenmawr post-tectonic Caledonian microdiorite stock gave an age of 375 ± 17 million years from a sample in which the feldspars were not quite fresh. Two potassium-feldspars from the pre-Cambrian Coedana granite of Anglesey, which was strongly sheared and chloritized by Caledonian movements gave ages of 377 ± 17 and 401 ± 11 million years. These must be regarded as minimum ages, as slow loss of argon from feldspar occurs over geological time. Two measurements on the Holyhead Dyke and one on the Llandegai sill gave Caledonian ages of 407 ± 22, 415 ± 33 and 401 ± 29 million years respectively, and the strongly sheared Uriconian basic acid igneous complex of Stanner Rocks in the Church Stretton Fault zone gave a minimum age of 418 ± 23 million years from a whole rock sample.

Pre-Cambrian Ages. Only one rock of this group produced a pre-Cambrian age on analysis. This is the remarkably fresh Uriconian basalt from Leaton Quarry, near Wrockwardine in Shropshire, which gave an age of 638 ± 81 million years. This rock forms part of the Caledonian foreland to the south-east of the Church Stretton tectonic line and appears to have largely escaped the full force of the Caledonian deformation. The rocks in this quarry have been folded and faulted at some time, however, and the age obtained cannot be used to fix the date of the Uriconian vulcanism more closely within the pre-Cambrian.

Certain conclusions can already be drawn from this work. Potassium–argon ages obtained from rocks are shown once again to be strongly affected by later geological events which can cause partial or complete argon loss. Orogenesis or metamorphism causes complete loss of all accumulated argon, while faulting and mineralization cause argon losses of varying amounts depending on their intensity. Thus the ages obtained from North Wales are necessarily a record of later events rather than of original ages. Apart from the one rock sampled from outside the Caledonian mobile belt, no age earlier than that of the Caledonian deformation has been obtained. In North Wales the pre-Cambrian, Cambrian, Ordovician and Silurian rocks have all been subjected to strong Caledonian deformation, and this event is therefore the

oldest for which an age can be expected by this method. Measurements in other areas have suggested that the main-Caledonian movements occurred some 420 million years ago. The age results from North Wales indicate that the principal Caledonian movements and magmatism took place some 400–420 million years ago. This would be compatible with the geological evidence which suggests that the folding began during the Salopian (producing submarine slumping and facies changes) and reached its greatest intensity towards the end of the Silurian. Uplift was probably earlier and more intense in the north-west (Anglesey) than in the south-east (Shropshire). Folding movements continued in the middle Devonian and these may be represented by the Penmaenmawr age of 375 ± 17 million years as late folds can be recognized near this intrusion.

But for later Variscan and Tertiary events the older rocks of North Wales should show uniformly Caledonian ages. In the vicinity of Variscan faulting and hydrothermal mineralization and close to Tertiary intrusions partial or complete argon loss has resulted in further apparent age reductions. Ages obtained in the range 265–280 million years are clearly related to the main end-Carboniferous (Saalic) Variscan movements, post-tectonic granitic activity and mineralization, which in North Wales mainly took the form of major north-east–south-west faulting, the faults then acting as channels for localized hydrothermal mineralization. The areal pattern of potassium–argon ages will enable these faults and zones of mineralization to be closely delimited. The effects of the early Tertiary magmatism were very local in North Wales, but represent the third event recorded by the age determinations.

Intermediate ages between these three dated events represent partial losses of argon and are not significant.

IN VITRO CYTOTOXIC EFFECT OF ISOANTIBODY MEASURED AS ISOTOPE RELEASE FROM LABELLED TARGET CELL DNA

By PROF. GEORGE KLEIN
Department of Tumor Biology, Karolinska Institutet
AND
DR. PETER PERLMANN
Wenner-Gren Institute, University of Stockholm, Stockholm

THE mechanisms of tissue damage in the homograft reaction are poorly understood. Although the destruction of the grafted tissue is most likely the end result of a large number of different types of reactions, it is commonly assumed that the interaction of antigen carrying (or producing) graft cells with either host antibodies or sensitized host lymphoid cells plays a predominant part in this connexion.

The mechanism of cytotoxic damage of target cells by antibodies can be studied *in vitro* in various ways. Antibodies are known to attach to the cell surface which changes its ultrastructure and probably becomes more fragile[1]. However, cell lysis is usually not observed unless complement is also present. The predominant expression of cell damage is an irreversible change in permeability of the surface of the affected cells[2]. This change results in a rapid equilibration of low-molecular substances between cell interior and outer medium. Therefore, the cytotoxic effects of antibodies can be easily studied by measuring the penetration of a dye into the damaged cells or by following the release of low-molecular substances from the cells[3]. Moreover, provided the concentration of stabilizing high-molecular substances in the medium is insufficient to counteract the imbalance of the osmotic equilibrium, the cells will also release a great deal of their cytoplasmic ribonucleic acid and protein[2]. If these components are labelled with an isotopic marker, their leakage into the medium can be easily followed[4].

The isotope method provides a convenient approach for investigations on the mechanism of immune cytotoxicity. However, under certain experimental conditions, it is difficult to avoid a cytoplasmic label leaking out to a certain extent from the control cells as well[5]. For quantitative studies of target cell damage due to immunological reactions, it would be desirable to reduce the non-specific background to a low level; this may result in some loss of sensitivity but can be useful as a complement to already existing techniques. The work recorded here represents an attempt to determine if this purpose could be achieved by labelling the DNA of the target cells with ^{14}C-thymidine. It has been known for some time that DNA is not released from the cells under the conditions described above, where the cells lose a great deal of their cytoplasmic RNA and protein[3,6,7]. However, it was expected that a release of DNA from immunologically affected target cells could be induced experimentally.

In a first series of experiments, isotope release from fresh and heat-killed ascites tumour cells was measured under various conditions. Cells of the ascites lymphoma *6C3HED* were labelled *in vivo* by injecting 0·2 μc. of thymidine-2-^{14}C (Amersham, England; spec. activity 0·1 mc./0·83 mg) intraperitoneally into *C3H* mice inoculated with the tumour 6 days earlier. The cells were harvested 48 h later. The ascitic fluid was divided into

three main portions. One contained the fresh, untreated cells, the second cells killed by heat (30 min incubation at 56° C) and the third cells stored at +4° C overnight. Subsequently, each sample was divided into four parts each containing approximately 10^3 cells, although the distribution of cells between samples was unequal owing to cell clumping. One part was treated with trypsin (0·25 per cent trypsin, dissolved in balanced salt solution) for 30 min at room temperature under gentle stirring, one with deoxyribonuclease under the same conditions (0·01 per cent, Sigma Chemical Co., St. Louis, Mo.), one with a mixture of trypsin and deoxyribonuclease, while one was left untreated in the refrigerator. In addition, the fresh cells were exposed to sodium deoxycholate in one sample (1 per cent in balanced salt solution). Afterwards, all samples were centrifuged (2,000 r.p.m., 10 min) and the supernatants were separated from the cells. Radioactivity was measured, at infinite thinness, with a thin-windowed Geiger–Müller tube in an automatic gas flow counter, after drying and plating of aliquots as described previously[5]. The values in the tables are expressed as the total radioactivity (c.p.m.) present in cells + medium. The relative release represents the percentage of radioactivity in the medium as related to the total activity in cells plus medium.

It appears from the typical and regularly reproducible experiment illustrated in Table 1 that fresh cells showed little tendency to release isotope into the supernatant, even when treated with deoxyribonuclease, trypsin, or both. The cells stored overnight in the refrigerator behaved like the fresh cells. This was in agreement with the results of supravital staining tests with eosin[8] which did not indicate more cell damage than approximately 7 per cent compared to the fresh controls (which contained 8–12 per cent eosin-stained cells themselves). However, when the cells were lysed with the surface-active sodium deoxycholate, almost half of their isotope content was released. Heat-killed cells did not release substantial amounts of isotope unless treated with trypsin, which induced them to release about two-thirds of their total isotope content in this experiment. In some other experiments, up to 90 per cent of the nuclear isotope was liberated. Deoxyribonuclease had no such effect in any of the cases studied.

The results of these experiments indicated that trypsin treatment may be useful in inducing isotope release from dead or damaged cells which would otherwise retain their DNA. In the following series of experiments an attempt was therefore made to apply this method for the demonstration of the cytotoxic effect of anti-H-2 isoantisera. Labelled target cells, known to be sensitive to antiserum, were exposed to it, in the presence of fresh guinea pig serum as the source of complement. Afterwards, they were treated with trypsin and isotope release was measured. Control cells were treated with normal mouse serum and complement. Isotope release was also measured in an aliquot of each sample after incubation of the target cells with balanced salt solution without trypsin. As a further control, the number of cells killed by isoantiserum and complement was also estimated by the supravital eosin-staining method of Schrek[8].

Three representative experiments, performed with a suspension of normal lymphoid cells and with two different lymphomas, are shown in Table 2. As will be seen, when the antiserum-treated cells were exposed to trypsin, the cytotoxic effect of the anti-H-2 isoantibodies could be easily detected. Moreover, the cytotoxic indices obtained very closely paralleled those calculated from the results of the eosin tests.

Preliminary experiments with another tumour (the *MC1M* ascites sarcoma), under the present conditions resistant to the cytotoxic action of anti-*H*-2 antibody as judged from the eosin test[9], have so far given negative results. This was also the case when tumour cells were similarly incubated with an excess of lymphoid cells derived from the lymph nodes and spleens of appropriately sensitized mice. Such cells are known to neutralize target tumour cells so that they will not grow when implanted afterwards into neutral hosts[10]. They also seem to exhibit visible cytopathogenic effects when added to tissue cultures of the target cells in long-term (24–48 h) experiments[11]. As reported previously[12] in experiments similar to those described here but in which a cytoplasmic-labelling technique was used, a specific release of isotope from the target cells into the medium was noted after 1–2 h of incubation with lymph node cells from sensitized animals. Further experiments will have to be carried out to decide whether the present failure was due to technical inadequacies or to real differences in the cytotoxic mechanisms as revealed by the different techniques.

In conclusion, it may be said that these experiments demonstrate that trypsin treatment of cells damaged by heat or by specific antibodies leads to the release of considerable proportions of nuclear DNA. Unless a more complete dissolution of cellular membranes is brought about by sodium deoxycholate, DNA is not released without trypsin treatment. This confirms the findings of previous authors[3,6]. Antibodies plus complement

are known to produce 'functional' holes in the outer cell membrane so that large molecules and even ribosomes as large as 150 Å in diameter may escape from the interior[7]. At present we do not know whether trypsin acts by causing a more complete destruction of the outer cell membrane or by attacking the nucleus in a more direct fashion. Whatever the mechanism, the present method seems easily applicable to measuring cytotoxicity in a highly specific manner and in a variety of immunological systems.

RADIOSENSITIVE MOLECULAR WEIGHT OF SINGLE-STRANDED VIRUS NUCLEIC ACIDS

By Dr. WILLIAM GINOZA
Pennsylvania State University, University Park, Pennsylvania

THE action of ionizing radiation on the macromolecules of importance in biology has been studied intensively for many years. Work with enzymes, proteins in general and nucleic acids has shown that ionization within the molecule leads to a drastic change in the biological behaviour. The idea that the statistical distribution of ionization can be used for determining the dimensions of macromolecules has been developed by Lea[1] and Pollard, Guild, Hutchinson and Setlow[2].

The development of this interesting and simple idea was followed, however, by clear indications of ways by which radiation action can be modified, notably temperature[3,4] and added protective substances[5–8]. Simple 'target' analysis thus has become a subject of some question. This fact need not, of itself, be uninformative, but it is disquieting, and forces an element of sophistication into radiation analysis which is not desirable.

Among the macromolecules which have recently received considerable study are single-stranded nucleic acids from viruses and the viruses themselves[9–14]. Such single-strand nucleic acids must be intact to function biologically, and, moreover, they possess no secondary structure that is functionally significant[10,11]. Thus an ionization, which in a covalently bonded structure must be considered as shared by the whole molecule, will cause at least one highly reactive and hence alterable bond in the structure. It is important to consider the reaction path of such an ionized molecule, since a given path can lead to a permanent alteration and hence inactivation or in certain instances, not desirable for target analysis, restitution of the molecule to its original functional form. The necessity for complete physical and chemical integrity for a particular biological function makes single-strand nucleic acids clear examples of the applicability of target analysis and a study of several of these is clearly of interest.

We have previously studied tobacco mosaic virus (TMV) and TMV-RNA[6]. To this are now added $\varphi X174$ and $\varphi X174$-DNA, which have been characterized by Sinsheimer[13] and $R17$ and $R17$-RNA. The latter virus is a small spherical bacteriophage recently isolated and characterized by Paranchych and Graham[15] and is closely related to $f2$ bacteriophage of Loeb and Zinder[16]. The investigation was divided into three parts: (*a*) an examination of the validity of target analysis for the nucleic acid alone; (*b*) an examination of whether the capsulation of the nucleic acid by protein has any effect on the analysis; (*c*) an examination of the nature and extent of protection against or potentiation of radiation action by agents in the medium in which viruses are irradiated.

For enzymes and simple viruses, the inactivation process generally obeys the expression $N/N_0 = e^{-kD}$, where N/N_0 is the fraction surviving a 'hit' after a given dose, D, measured in roentgen, r, and k is the apparent target mass. A 'hit', as the expression implies, is a quantized kill event, but just what this event precisely entails in terms of amount of energy absorbed per target molecule and how these discrete ionization events are spaced in the experimental samples has remained uncertain. By the latest approximation a gram of tissue or virus exposed to 1 r. absorbs 87 ergs (ref. 17); this energy is absorbed not homogeneously but primarily as discrete ionization events called primary ionizations or ion clusters, each of which, as experimentally determined recently in solids by Rauth and Hutchinson[18], have an average energy of about 60 eV. If we accept these values, then 1 r. will deposit $9{\cdot}0 \times 10^{11}$ ionization events per gram of target material. Inasmuch as the foregoing expression also implies that the 'hit' events are statistical in nature, so it is necessary to assume that the spacing of the ionization events must be randomly distributed. This seems not strictly true as ionization in fact occurs along tracks. But the tracks themselves occur randomly, and if the average distance between ionization clusters along a given track is large compared with the target dimensions, then effectively the clusters will be random in space and each cluster will constitute an independent kill event. It is reasonable to assume that the action probability for simple biological systems studied here is unity or close to unity inasmuch as the release of energy in the ionization cluster involves 60 eV. A model of Samuel and Magee[19] indicates that each cluster is confined on the average within a volume of 7 Å radius. The contribution of excitation energy to lethality is considered small relative to the ionization energy[2].

The irradiation sources used here are a 50 kV Picker X-ray machine equipped with a beryllium window and a cobalt-60 source for the 1 MeV gamma ray. Both sources were calibrated by Fricke chemical dosimetry[20]. All samples were irradiated over an atmosphere of air. For X-irradiation 0·05-ml. samples of virus or nucleic acid are placed on polyethylene disks 2 mm thick, put in an aluminium chamber, the top of which is covered with a thin mylar film and either dried or frozen prior to irradiation. The X-ray machine was operated at 50 kV with a dose rate usually of 23 kr./min. Control samples were placed away from the beam and covered with a lead shield 3 mm thick. For γ-irradiation, 0·3-ml. samples were placed in small glass test tubes, frozen and set in a regular cylindrical array around the cobalt source and kept frozen in crushed solid carbon dioxide during the irradiation. The dose rate was 6·7–7·4 kr./min. TMV was assayed as previously described[6]. $R17$ and $\varphi X174$ were

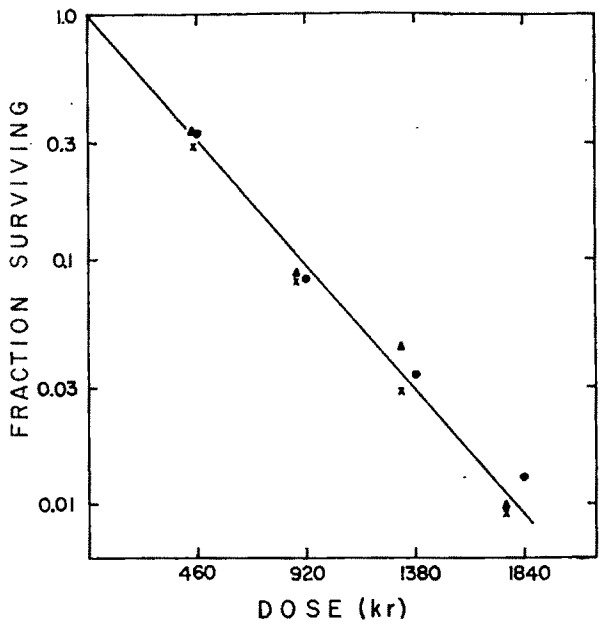

Fig. 1. X-ray inactivation curve of φX174 suspended in 1 per cent tryptone broth (Difco). Bacterial lysate in broth containing 1×10^{10} plaque-forming units/ml. of the virus was serially diluted in tryptone broth to 1×10^{8} pfu/ml. 0·05-ml. samples of the final dilution were either frozen or dried on plastic disks for the irradiation ×, Irradiated dry at 25°–30° C (average of 7 experiments); ▲, irradiated frozen at −60° C (average of 3 experiments); ●, irradiated frozen at −180° (average of 3 experiments). A 50 kV Picker beryllium window X-ray machine was operated at maximum voltage with a current of 7m.amp, dose rate at 23–24 kr/min

assayed on *Hfr* strain of *Escherichia coli* and *E. coli C* respectively, and their nucleic acids on the protoplasts of their respective hosts. The method of Gutherie and Sinsheimer[21] was followed for the assay using protoplasts, except that 30 per cent sucrose was substituted for bovine serum albumin.

Fig. 1 shows the summary of the X-ray inactivation curves of φX174 in tryptone broth from several experiments conducted over a temperature range of −180°–+30°. It can be seen that the experimental points fit a one 'hit' survival curve over at least two logarithmic decades and its slope indicates a D_{37} of 386 kr. Assuming the figures of 60 eV per ionization event and 87 ergs/g/r., we get $3{\cdot}47 \times 10^{17}$ ionization events per gram of the radiosensitive portion of the virus to effect reduction of the viral population to e^{-1}. This leads to a target molecular weight of $1{\cdot}74 \times 10^{6}$, which coincides with the physical molecular weight found for the virus DNA by Sinsheimer[13]. A range in values between 1·66 and $2{\cdot}02 \times 10^{6}$ is obtained in 13 separate experiments. It is to be noted that the target sensitivity remains invariant over the experimental temperature range. Pollard and Dimond observed earlier that over a temperature range of 20°–73°, TMV sensitivity to deuteron bombardment remains constant[23]. This is in contrast to the case of bacteriophage *T*1 and of enzyme inactivation using densely ionizing radiation[3,4,22]. This indicates a difference between these single-strand materials and other double-strand DNA or folded protein.

The dose response curves of φX174 and of its free DNA irradiated by cobalt-60 in tryptone broth at −60° are plotted in Fig. 2. A close fit of points for both the intact virus and its free DNA to a single slope is obtained. Moreover, the slope shows a D_{37} of $3{\cdot}68 \times 10^{5}$ r. for a molecular weight of $1{\cdot}82 \times 10^{6}$, which agrees closely with the result shown in Fig. 1 for X-irradiation, indicating good agreement between the two irradiation sources with regard to the dose calibration and effectiveness per r. absorbed. The result also confirms our earlier conclusion drawn from the TMV system that the inactivation of the virus by X-rays is a consequence of a single ionizing event occurring anywhere on the nucleic acid moiety of the virus[6].

Fig. 3 summarizes the results of irradiating *R*17 and *R*17-RNA, both frozen in tryptone broth at −60° by γ-rays at a dose rate of 7·4 kr./min. The D_{37} for this system is 836 kr., giving a radiosensitive molecular weight of $0{\cdot}8 \pm 0{\cdot}2 \times 10^{6}$, in good agreement with a value of $1{\cdot}0 \times 10^{6}$ we obtained by X-irradiation and with the physical molecular weight of $0{\cdot}92 \pm 0{\cdot}2 \times 10^{6}$ reported by Mitra *et al.* for the viral RNA[24]. The physical molecular weight of the intact virus calculated from sedimentation and diffusion data is $4{\cdot}9 \times 10^{6}$ (ref. 24).

We have previously noted that when TMV-RNA or catalase is irradiated while suspended in 2 per cent reduced glutathione (GSH), their sensitivity to X-ray inactivation is decreased by a factor of 2 (refs. 6 and 8). Fig. 4 shows the same effect with the φX174 and its free DNA is protected to the same extent, as is also true for the *R*17 system, indicating that the reaction is quite general, even to the extent of protection. This reaction is most likely a transfer of electrons from the reduced glutathione molecules to the ionized target, working in competition with the surrounding oxygen molecules. Some of the hit targets are thus restored to their original state. In the absence of any protective agent, oxygen reacts with the metastable target (for example, carbonium ion) with

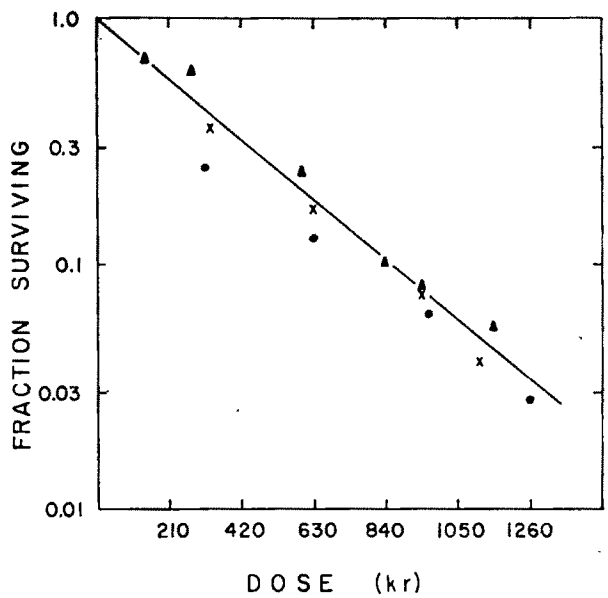

Fig. 2. Cobalt-60 inactivation curve of φX174 and φX174-DNA suspended in 1 per cent tryptone broth (Difco). 0·3-ml. samples were irradiated frozen at −60° C in glass test tubes ×, φX174; ▲, φX174 DNA, or at 30°–40° C., dried (●, φX174). Dose rate, 7·0–7·4 kr/min

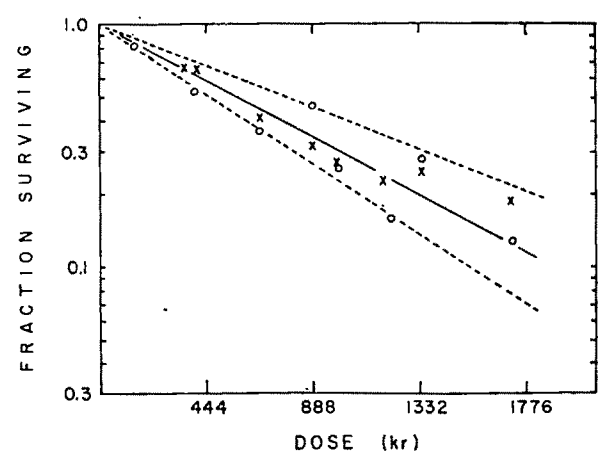

Fig. 3. Cobalt-60 inactivation of *R*17 (×) and *R*17 RNA (○) suspended and frozen at −60° C in 1 per cent tryptone broth (Difco). Upper dashed line is a slope calculated for a radiosensitive molecular weight of $0{\cdot}6 \times 10^{6}$ and the lower dashed line for $1{\cdot}0 \times 10^{6}$. Slope is exponential for at least 3 logarithmic decades in the case of X-ray inactivation

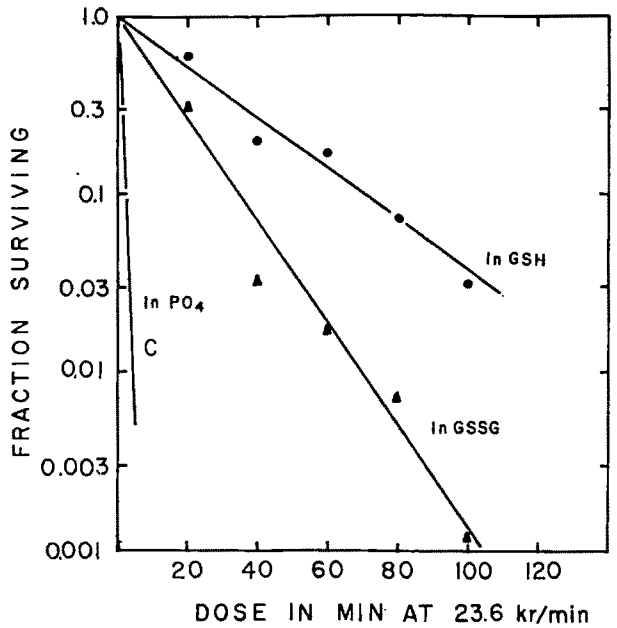

Fig. 4. Effect of 1 per cent reduced glutathione (GSH), 1 per cent oxidized glutathione (GSSG) and 0·1 M sodium phosphate buffer, *p*H 7·2 (curve *C*) on the sensitivity of φ*X*174 to X-irradiation. GSH and GSSG solutions were prepared in water and the *p*H adjusted to 6·8 with sodium hydroxide. The virus preparations in this case were irradiated dry at 25°–30° C

high efficiency forming an organic peroxide which is thought to be the principal lethal reaction[25]. In the target experiments recorded here, concentration of oxygen is not believed to be limiting because the samples are continually exposed to the atmosphere during preparation and irradiation. Moreover, the lifetime of the ionized targets while in a frozen or dried state is sufficiently long[26] to permit them to react with oxygen in the time intervening between the end of irradiation and the preparation of the samples for bioassay for the surviving population. Thus, the question of the diffusion rate of oxygen during irradiation is minimized at least under the conditions of our experiments. But, as we have shown earlier[6], glutathione must be present during irradiation to show the protective effect.

The protection is the same for the free nucleic acid as for the intact virus, indicating either that donor electrons can readily migrate through the protein shell of the virus or that the shell is not a barrier to the GSH molecules. On the other hand, the target sensitivity for either free DNA or intact virus suspended and irradiated in oxidized glutathione (GSSG) remain unchanged (Fig. 4), as might be expected, as when they are suspended in tryptone broth. This is found to be the case for TMV also.

A more serious kind of modification of target sensitivity is observed when either φ*X*174, *R*17 or their free nucleic acids are suspended in 0·1 *M* phosphate buffer, *p*H 7·2, as illustrated by Fig. 4, curve *c*, for φ*X*174. Here, as Brustad[22] has also noted, we see a striking potentiation of radiation effect, where the apparent target size is now ten-fold greater than the actual physical molecular weight. A similar effect is shown by biological materials irradiated in sodium acetate[27] and sodium chloride[6].

We have no explanation for the unusual sensitization seen here except to note that the effect: (1) is linearly dependent on the log of the concentration of phosphate buffer over the measured range of 10^{-3} to 10^{-1} molar; (2) persists after irradiation; (3) is depressed in the presence of added tryptone broth, suggesting that some reactive product is formed when this buffer is irradiated. TMV and TMV-RNA are much less sensitized than φ*X*174 and *R*17 by this buffer. This may be explained by the fact that, because of their lower plating efficiency, they must be irradiated at a concentration (> 1 mg/ml. versus 10^{-6} mg/ml. for φ*X*174 and *R*17) so high that self-protection against reactive phosphate products can be observed. This phenomenon was shown by Lea in experiments where TMV was irradiated in solution at various concentrations[1].

In Fig. 5 is shown the result of one single experiment wherein one series of TMV samples was irradiated at 2 mg/ml. with γ-rays in the presence of 0·1 M phosphate buffer, *p*H 7·2, and another in 1 per cent tryptone broth. It is obvious that there is no phosphate effect of the magnitude seen in the φ*X*174 system. It shows also that the radiation sensitivity is not modified by tryptone broth; points fit reasonably well with the curve obtained from a more extended work reported earlier[6] for both this virus and its free infectious nucleic acid. It is to be noted that by assuming the new and independently derived figures of 60 eV/pi and 87 ergs/g/r., a radiosensitive molecular weight of $2{\cdot}2 \times 10^6$ is obtained from this slope which indicates a D_{37} of $3{\cdot}0 \times 10^5$ r. The reported physical molecular weight is between $1{\cdot}9 \times 10^6$ (ref. 9) and $2{\cdot}2 \times 10^6$ (ref. 28). The target size is also consistent with the dimensions derived from the earlier radiation analyses of Lea *et al.*[1], Pollard and Dimond[23] and Buzzel, *et al.*[29].

While the phosphate and glutathione effects clearly point to the hazards involved in attempting to estimate target molecular weight of virus and enzymes in their impure state or in the cell, it must be emphasized that these demonstrations of protection and potentiation are made possible by exposing the target materials to high concentration (10^8–10^{15} molar excess over virus) of pre-

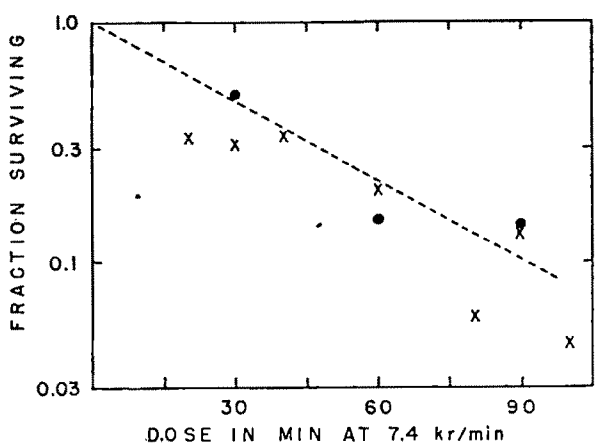

Fig. 5. Inactivation by cobalt-60 γ-ray of TMV frozen at −60° C in 0·1 M sodium phosphate buffer, *p*H 7·2 (×) and in 1 per cent tryptone broth (Difco) (●) at 2 mg virus/ml. The dashed slope (see text) shown was obtained from the earlier results of X-ray inactivation of TMV and TMV–RNA suspended and frozen in distilled water (ref. 6)

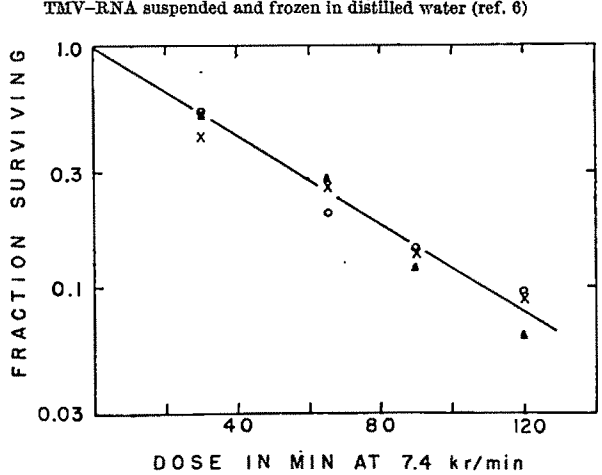

Fig. 6. Media effects on the sensitivity of φ*X*174 to cobalt-60 γ-irradiation. ○, Irradiated frozen at −60° C in 4 per cent nutrient broth (Difco); ▲, in 4 per cent tryptone broth; ×, in 30 per cent *E. coli* lysate suspended in water

selected chemical environment. Of course, the presence of radiation sensitizing micro-environment around a target inside a cell can never be ruled out; for example, Braams *et al.*[27] have shown a two-fold protection of invertase when it is irradiated in yeast cells, which they ascribed to the presence of substances rich in sulphydril groups. But Pollard *et al.*[2] demonstrated that succinic dehydrogenase and cytochrome oxidase have the same target sensitivity in or out of the *B. subtilis* cells. In Fig. 6 are plotted the present results of irradiating, at $-60°$, 1×10^9 plaque-forming units of $\varphi X174$ in bacterial lysate, which prior to irradiation is re-suspended in 30 per cent *E. coli* lysate, 4 per cent tryptone broth and 4 per cent nutrient broth. Following irradiation, the different sample series were diluted a thousand-fold into tryptone broth for assay of survivors. It is seen that the sensitivity of the virus in all media indicate closely similar target molecular weight of $1{\cdot}9–2{\cdot}0 \times 10^6$, which is well within the usual error of the assay observed in the foregoing experiments.

It can be demonstrated in all three cases of modification of direct action worked on or mentioned here that the protective or potentiating effect is dependent on the concentration of the added modifying agents[8,27]. The foregoing experiments thus suggest that, regardless of the purity of the initial virus preparation, a simple serial dilution of target samples into such innocuous media (for example, see legend, Fig. 1) as tryptone broth, nutrient broth and GSSG for irradiation would obviate any potential effect of the medium. (These media are not unique in this property since results clearly show that the heavy protein matrices of viruses do not modify the radiation sensitivity of the nucleic acid they envelop.) An empirical step of serial dilution, combined with some biological calibration of target procedure using viruses and nucleic acids of known molecular weight, should be effective in obtaining dependable target molecular weight very simply.

Taking due cognizance of radiation modifying effects, valid radiation target molecular weights can be obtained relatively simply for small viruses and their free nucleic acids with an accuracy expected from conventional physical methods. The combined experimental results obtained here from both γ- and X-irradiation bear out the assumptions that: (1) 60 eV constitute a killing event and this quantum of energy has an efficiency of 1; (2) the number of lethal events does not exceed the number of ionizing events. The results are also consistent with the assumption that an ionized target subsequently reacts in some way, probably with oxygen[25], with high efficiency and only then is the 'hit' target scored as a kill. The independence of target sensitivity with temperature between $-180°$ and $+30°$ fits the expectation for sparsely ionizing radiation that the lethal event in the nucleic acids is a direct result of ionization and not of thermal effects arising from absorption of excitation energy.

I thank Dr. E. C. Pollard for useful discussions. I also thank Drs. Sam G. Wildman and John S. Boyle, who provided assay plants, and Drs. Robert L. Sinsheimer, Richard Boyce and William Paranchych for the supply of bacteriophages.

QUANTITATIVE ESTIMATION AND IDENTIFICATION OF BARBITURATES IN BLOOD IN EMERGENCY CASES

By Dr. HAROLD V. STREET and COLIN McMARTIN
Department of Forensic Medicine, University of Edinburgh

ANY method for the determination of barbiturate in a patient's blood must, to be of value to the clinician and, hence, to the patient, fulfil three conditions. First, it must be capable of yielding results sufficiently rapidly to allow the clinician to commence treatment before the patient's clinical condition deteriorates. By rapidly, is meant that the time required for the analysis, that is, quantitative assay of the barbiturate and its identification, should be of the order of 1 h. This would be the time reckoned from receipt of the blood by the laboratory to completion of analysis.

Secondly, the quantitative estimation must be precise to within ± 10 per cent. Greater variation than this might give misleading results if serial analyses were being performed with short time-intervals.

Thirdly, in order to be able correctly to interpret the results of the quantitative assay, it is necessary to know which particular barbiturate is present in the patient's body. In the past, it has not been possible to identify the barbiturate within 1 h, but the introduction by Street[1–4] of paper-partition chromatography at elevated temperatures has enabled the more commonly used barbiturates to be identified in a blood extract within 20 min.

Specificity is a further criterion which must be satisfied and which may be achieved in high degree by a combination of several factors. By carrying out a classical separation of a blood protein-free filtrate, a fraction can be obtained which contains only barbiturates and other weak acids. If ultra-violet spectrophotometry is used for the quantitative assay of this weak acids fraction, it is possible to arrange the conditions so that an absorption maximum occurs at a wave-length which is peculiar to a particular group of barbituric acid derivatives. For example, the

5 : 5-disubstituted barbiturates, which incidentally are the group most commonly encountered, display the characteristic phenomenon of exhibiting at *p*H 11 a peak at 240 mμ which disappears when the solution is brought to *p*H 2.

The recent work of Street and McMartin[5] has shown that a further step towards the unequivocal identification of individual barbiturates can be taken by heating at 100° C an aliquot part of the weak acids fraction with concentrated sulphuric acid for 3 min and examining the ultra-violet spectrum of the products.

Chromatography at about 90° C on tributyrin-impregnated paper with an aqueous solvent separates most of the more commonly used barbiturates in 15 min and, together with the ultra-violet spectra at *p*H 11 and *p*H 2, and the results of sulphuric acid treatment, provides a rapid procedure for the identification and assay of blood barbiturates.

The method we recommend involves preparation of a protein-free filtrate of blood. For this purpose we have modified slightly the procedure described by Folin and Wu[6] and have used Curry's[7] suggestion to heat the tungstic acid–blood mixture. The acidic and the neutral compounds are extracted from the acid filtrate by shaking with ether. Strong acids such as salicylic acid are removed by extraction of the ether with a *p*H 7·3 buffer. By shaking the ether with alkali, the neutral compounds are left in the organic phase and the weak acids extracted into the aqueous phase. Acidification of the alkaline medium and re-extraction into ether yields a fairly pure weak acids fraction.

This fraction is then divided into three parts. One portion is used for quantitative estimation by ultra-violet spectrophotometry; another portion is used for elevated-temperature chromatography; a third portion is taken for treatment with sulphuric acid to assist further in identification of the barbiturate.

De-ionized water is used throughout. The following reagents are needed:

(1) 10 per cent (w/v) sodium tungstate solution. Dissolve 100 g of $Na_2WO_4 2H_2O$ in water to 1 litre.

(2) Sulphuric acid solutions, 2 per cent, 10 per cent and 6 N. Pour 20 ml., 100 ml. and 167 ml. respectively of 'AnalaR' concentrated sulphuric acid into water and dilute to 1 litre.

(3) Ether. Shake 2½ litres of 'anæsthetic ether' (diethyl ether) with 50 ml. portions of 10 per cent sodium hydroxide solution until the alkaline extract is colourless. Wash the ether with water until the washings are free from alkali. Store the washed ether in a dark room.

(4) Phosphate buffer, *p*H 7·3 (0·5 M). Mix 80 ml. of 0·5 M $Na_2HPO_4.2H_2O$ (89 g/l.) and 20 ml. of 0·5 M KH_2PO_4 (68 g/l.).

(5) Phosphate buffer, *p*H 7·4 (M/15). Mix 80·8 ml. of M/15 $Na_2HPO_4 \cdot 2H_2O$ (11·9 g/l.) and 19·2 ml. of M/15 KH_2PO_4 (9 g/l.).

(6) Sodium hydroxide solution (2·5 per cent). Dissolve 25 g sodium hydroxide pellets in water and dilute to 1 litre.

(7) Sodium sulphate (anhydrous).

(8) Ammonia solutions (0·5 N and 4 N). Dilute 7·1 ml. and 57 ml. respectively of concentrated ammonia solution (sp. gr. 0·88) to 250 ml. with water.

(9) Tributyrin solution. 10 per cent (v/v). Dilute 25 ml. of tributyrin (glyceryl tributyrate) to 250 ml. with acetone.

(10) Sulphuric acid, 95 per cent. Carefully add 5 ml. of water to 95 ml. of 'AnalaR' concentrated sulphuric acid. Mix thoroughly and store in a well-stoppered glass bottle.

(11) Potassium permanganate solution (0·1 per cent (w/v)). Dissolve approximately 100 mg of potassium permanganate crystals in 100 ml. of water. Prepare freshly as required.

To 65 ml. of water contained in a 40 mm × 240 mm test-tube add 5 ml. of blood. Mix and allow to stand for at least 2 min for the cells to lake. Add 15 ml. of 10 per cent sodium tungstate solution, mix and then run in 15 ml. of 2 per cent sulphuric acid solution. Stopper the tube and shake the mixture until its colour changes from red to reddish-brown or brown. This takes about 1 min. Remove the stopper and immerse the tube in a bath containing vigorously boiling water for 3 min. The contents of the tube must be beneath the water surface. Remove the tube and filter the hot mixture through a Whatman No. 1 paper into a 100-ml. measuring cylinder. Cool the filtrate and measure its volume (usually about 90 ml.).

Extract the cooled filtrate by shaking with 50 ml. of washed ether. Allow the liquids to separate and run off the aqueous layer. Shake the ether phase with 10 ml. of 0·5 M phosphate buffer, *p*H 7·3 and discard the aqueous layer. Extract the organic phase with two separate 3-ml. portions of 2·5 per cent sodium hydroxide solution. Run the alkaline extracts immediately into 5 ml. of 10 per cent sulphuric acid solution contained in a clean separating funnel. Shake this acidified solution with 25 ml. of washed ether. Discard the aqueous phase and dry the ether layer by shaking with about 2 g of anhydrous sodium sulphate. Pour the ether extract into a 25-ml. measuring cylinder and divide into three separate portions in 50-ml. flasks *A*, *B* and *C* as follows: Into each of flasks *A* and *C* place two-tenths of the ether extract (*N.B.*, flask *C* should be round-bottomed). Into flask *B* place six-tenths of the ether extract. Evaporate the contents of each flask to dryness on a boiling-water bath. Remove the flasks from the bath immediately the ether has evaporated and place them on a cold slab of metal to cool.

Flask A. Dissolve the residue in 3 ml. of 0·5 N ammonia solution. Measure 2·5 ml. of the solution into a silica or quartz cuvette (1 cm light path) and plot its absorption curve against 2·5 ml. of 0·5 N ammonia solution from 200 to 350 mμ. Add 0·5 ml. of 6 N sulphuric acid to both 'test' and 'blank' cuvettes. Mix the solutions and replot the ultra-violet spectrum. Let R_{OH} be the absorbance of the ammoniacal 'test' solution at 240 mμ and R_H the absorbance of the acid 'test' solution at 240 mμ, then:

$$\text{blood barbiturate} = \frac{(R_{OH} - R_H)}{S} \times \frac{3}{50} \times \frac{10}{2} \times \frac{100}{F} \times \frac{100}{5} \text{ mg/100 ml.}$$

$$= \frac{(R_{OH} - R_H)}{S \times F} \times 600 \text{ mg/100 ml.}$$

where $S = (R_{OH} - R_H)$ for standard barbiturate solution (see below) and F = ml. of tungstic acid filtrate used.

If the ultra-violet spectrum shows no maximum at 240 mμ, it may be assumed that barbiturate is either not present in the blood sample being analysed or is present in insignificant amount.

Flask B. Dissolve the residue in about 6 drops of chloroform and transfer the solution with a glass capillary tube to the starting line of a previously prepared sheet of tributyrin-impregnated Whatman No. 3 paper. (Dip the papers in a 10 per cent (v/v) solution of tributyrin in acetone, press between sheets of filter paper and allow to dry in air. Papers should be impregnated not more than 2 h before being used) (Fig. 1*a*). As reference standards, put about 2 μl. of 2 per cent ethanolic barbiturate solutions also on the starting line. The size of spot should, preferably, be not greater than 3 mm diameter. A mixture of barbitone, phenobarbitone, butobarbitone and pentobarbitone may be placed on one side of the unknown spot and a mixture of amylobarbitone and quinalbarbitone on the other side. Fold the paper into a cylinder, fasten with a paper-clip as shown in Fig. 1*b* and carry out chromatography for 17 min.

This is done by placing the paper cylinder in a 2-litre beaker containing M/15 phosphate buffer *p*H 7·4. The beaker and buffer have, about 0·5 h previously, been put in an oven maintained at a temperature of about 95° C.

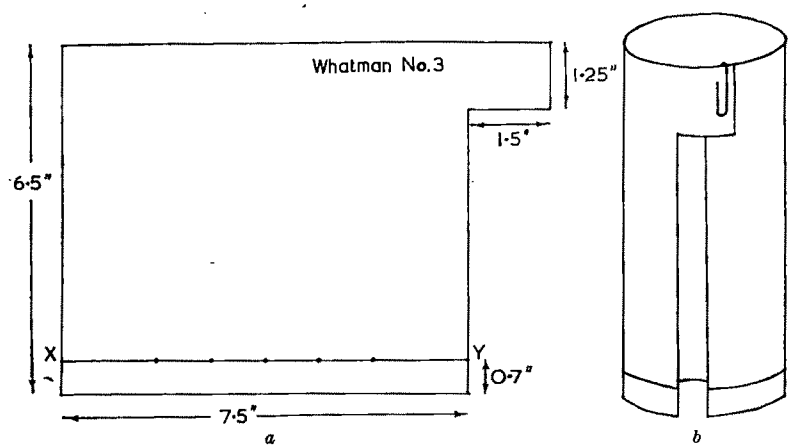

Fig. 1. *a*, Size and shape of Whatman No. 3 paper used for reversed phase paper chromatography at 95° C. After the paper has been impregnated with tributyrin, the compounds to be separated are applied at points on the line *XY*; *b*, paper folded into cylinder and fastened with a paper-clip prior to carrying out reversed phase chromatography at 95° C

A disk of plate glass smeared with silicone grease is used to seal the beaker. The amount of buffer in the beaker is such as to give a depth of about 3/8 in. of liquid. The paper cylinder is placed in the beaker without removing the beaker from the oven.

After 17 min, the solvent will have run about 5 in. up the paper from the starting line. Remove the paper from the beaker and examine in 254 mμ radiation (a Hanovia 'Chromatolite' lamp is suitable for this purpose). Expose the paper to ammonia gas and re-examine under the lamp. Note the position of any absorbing areas (Fig. 2).

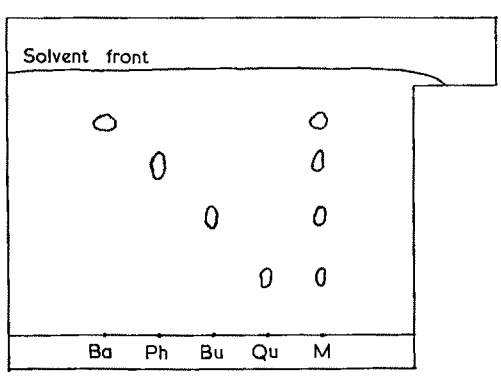

Fig. 2. Separation of four barbiturates by reversed phase chromatography at 95° C on Whatman No. 3 paper impregnated with tributyrin. Solvent, M/15 PO_4, *p*H 7·4; time of run, 17 min

Ba, barbitone; *Ph*, phenobarbitone; *Bu*, butobarbitone; *Qu*, quinalbarbitone; *M*, mixture of these four barbiturates

The paper may now be dried with a hair-dryer and then dipped in 0·1 per cent solution of potassium permanganate. Those barbiturates containing an unsaturated group in their side chain(s) will show up as yellow spots on a pink background.

Flask C. Add 0·2 ml. of 95 per cent sulphuric acid to flask *C*, stopper the flask and make sure that the acid is run over the residue. Heat the flask in boiling water for 3 min, cool and add 4 ml. of water. Pour the solution into a separating funnel, rinse the flask with 1 ml. of water and add this rinsing to the separating funnel. Shake with 25 ml. of ether and allow the layers to separate.

Aqueous phase. Run the aqueous phase into a graduated test-tube and pass a stream of nitrogen through the solution for about 2 min to remove the ether. Then add an equal volume of 4 N ammonia solution, mix and plot the absorption curve from 200 mμ to 350 mμ. Use silica or quartz cuvettes of 4 cm light path. Add 2·0 ml. of 6 N sulphuric acid solution and replot the absorption curve (Fig. 3). The 'blank' in this case is a mixture of 0·2 ml. of 95 per cent sulphuric acid, 5 ml. of water and 5·2 ml. of 4 N ammonia solution.

Ether phase. Dry the ether phase by shaking with about 1 g of anhydrous sodium sulphate, decant, and evaporate to dryness on a boiling-water bath. Remove the flask immediately the last drop of ether has evaporated. Cool the flask and dissolve the residue in 3 ml. of 0·5 N ammonia solution. Plot the absorption curve from 200 mμ to 350 mμ against 0·5 N ammonia solution. To 2·5 ml. of solution, add 0·5 ml. of 6 N sulphuric acid solution, mix and replot the absorption curve (Fig. 3).

A fuller description of the heating of barbiturates with sulphuric acid is given by Street and McMartin[5].

Standard curves should be constructed only from freshly prepared solutions.

Dissolve 20 mg of pure barbituric acid derivative in 200 ml. of 0·5 N ammonia solution. Add 1 ml. of this solution to 4 ml. of 0·5 N ammonia solution and plot the absorption curve from 200 mμ to 350 mμ. Use silica or quartz cuvettes of 1 cm light path. To 2·5 ml. of this solution add 0·5 ml. of 6 N sulphuric acid solution and replot the absorption curve.

The difference, *S*, between the absorbance in ammonia (R_{OH}) at 240 mμ and that in acid (R_H) at 240 mμ is used for calculation of the amount of barbiturate in blood (see foregoing), that is:

$$S = (R_{OH} - R_H)$$

For the 5 : 5-disubstituted derivatives, $S = 0{\cdot}9 \pm 0{\cdot}1$ (see also ref. 7).

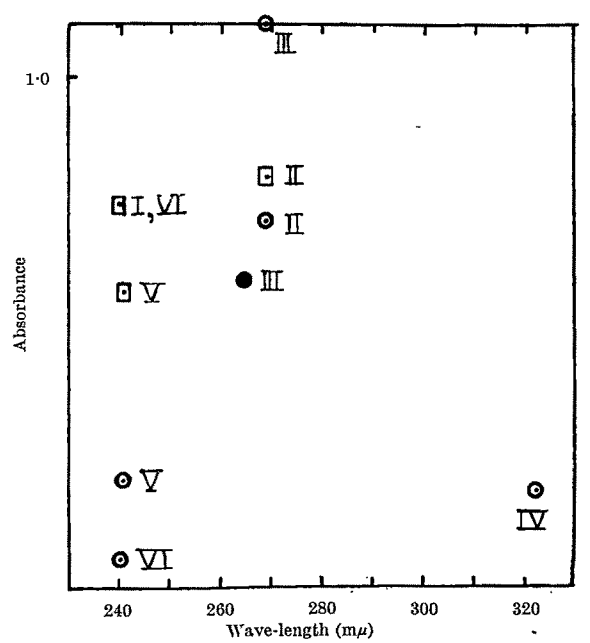

Fig. 3. Relative absorbances of products obtained from 50 μg of barbiturate subjected to treatment with sulphuric acid (see text)

Discussion

A diagrammatic plan of the various steps in the analysis is shown in Table 1. Part I of the analysis, which is to prepare a protein-free filtrate of the blood and produce a partially purified ether extract of this filtrate requires 30 min. Parts II, III and IV need 5, 25 and 20 min, respectively. It is suggested that one worker carry out parts I and IV and another worker do parts II and III. In this way, a complete analysis can be carried out in 55 min.

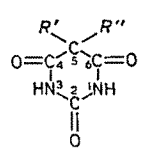

Table 1

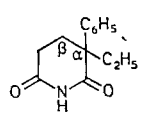
There are several steps in the procedure which require amplification and emphasis. Thorough washing of the ether is essential for production of 'low blank readings'; loss of barbiturate can occur if, during evaporation of an ether extract, the flask is not removed from the bath immediately the last drop of ether has disappeared; it is imperative that the sulphuric acid added to flask *C* should come into contact with the whole of the residue; the filters used in the 'Chromatolite' 254 mμ lamp should be tested regularly with a spot of a known barbiturate on tributyrin-impregnated paper in the presence of ammonia gas. The 'life' of some of these filters may be as short as 800 h.

The limitations of the procedure are such that a level of 0·5 mg of barbiturate per 100 ml. of blood can just be measured quantitatively when starting with 5 ml. of blood but this concentration is insufficient for detection by chromatography of the residue in flask *B*. Above this level, no difficulty should be experienced with either the quantitative or qualitative estimation.

In the quantitative assay, it has been assumed that the barbiturates being measured are dialkyl derivatives substituted only on carbon atom 5.



This assumption has been made because the 5 : 5-di-substituted derivatives are in commonest use. However, 1 : 5 : 5-tri-substituted derivatives may occasionally be encountered. The *N*-methyl derivatives and also the thiobarbiturates (which are used exclusively as anæsthetics) may be distinguished by the wave-length of their absorption maxima at different *p*H values (Table 2). Chromatography provides confirmation.

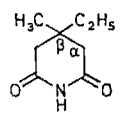


Table 2

Derivative	Wave-length maxima (mμ) at *p*H 2	at *p*H 11	at *p*H 14
1 : 5 : 5-	nil	245	245
5 : 5-	nil	240	255
Thio-	239,288	255,303	303

In the recommended method, no serious interference from substances which are not barbiturates will be encountered, and, in this connexion, only salicylates and glutarimides will, therefore, be considered. Salicylate will be removed by washing with the *p*H 7·3 buffer. If present in large amount, some will escape into the weak acids fraction and will be seen on the chromatogram in 254 mμ light as a light-blue fluorescent spot (R_F about 0·9) and will also distort the ultra-violet absorption curve. It is, therefore, wise to test a portion of the original blood sample with Trinder's[8] reagent. This takes only a few minutes and can be done while the tungstic acid/blood mixture is filtering. If the test is positive, then the excess salicylate can be removed by three washes with the *p*H 7·3 buffer. If Trinder's test is negative, the single wash with *p*H 7·3 buffer should not be omitted as this serves to remove some of the acidic fatty material encountered in all blood/tungstic acid filtrates. Of the glutarimides, only glutethimide and bemegride need be considered.

Glutethimide

Bemegride

In 0·5 N-ammonia solution, glutethimide and bemegride have absorption maxima at 235 mμ and 230 mμ respectively. The glutarimide ring is unstable in alkaline solution and both these compounds may be detected, and also estimated, by observing the decrease in absorbance (at the wave-length maximum) with time.

HÆMOSTATIC CHANGES ASSOCIATED WITH EXERCISE

By E. IKKALA and G. MYLLYLÄ
Finnish Red Cross Blood Transfusion Service, Helsinki
AND
H. S. S. SARAJAS
University Institute of Physiology, Helsinki, Finland

PHYSICAL exercise is known to affect the hæmostatic balance. Even if some hæmostatic indices have been found to behave inconsistently in response to exercise, possibly owing to technical differences, observations on the time of coagulation[1,2], like thromboelastographic results[2,3], have generally yielded evidence suggesting that exercise gives rise to hypercoagulability. Of the coagulation factors of the plasma, the levels of Factor V[2], Factor VIII (AHG)[4] and Factor XII (Hageman factor)[5] have been reported to be raised concurrently. The platelet count

has also been stated to increase[3,6], but the count appears to be rapidly restored in the post-exercise period[3]. On the other hand, physical exercise has been shown to increase fibrinolytic activity[5,7].

The work described here was undertaken to explore exercise-induced changes in all the main hæmostatic parameters, with reference also to their behaviour in the period following exercise.

The tests were made on 10 apparently healthy medical students. They were, after over-night fasting, subjected to 6 min heavy muscular exertion (1,250 kg. m./min) by use of a bicycle ergometer. Blood samples were taken before and immediately after the exertion, as well as 10, 30 and 60 min following completion of the work. The methods for the preparation of plasma and serum and for the clotting tests were, if not otherwise stated, those described previously[8]. The following tests were carried out: thromboelastography (Hellige), recalcification time, prothrombin consumption index, Quick thromboplastin time, platelet count[9], thromboplastin generation test, fibrinogen, prothrombin, Factor V, Factor VII-complex, $P+P$, Factor VIII[10], Factor IX[10], Factor XI+XII ('contact factor' by Waaler's method)[11], and fibrin plates[12]. The plates used were as follows: (1) activator (+plasmin): euglobulin on unheated plates; (2) plasmin: euglobulin on heated plates; (3) plasminogen: euglobulin+streptokinase (8,000 units per ml. of euglobulin) on heated plates.

An outline of the behaviour of the coagulation parameters before and following the performed work is given here. The changes observed are shown in Fig. 1.

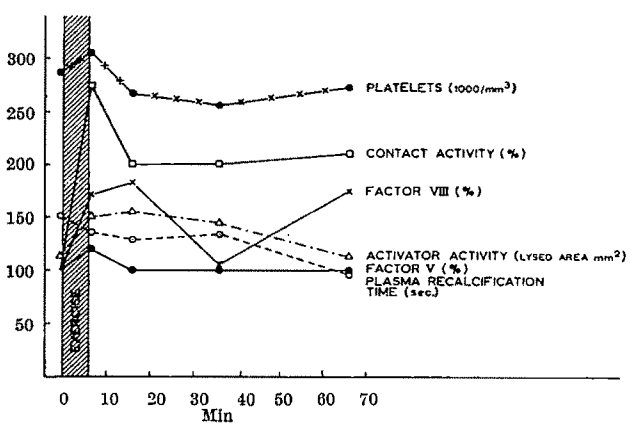

Fig. 1. Behaviour of the coagulation parameters exhibiting most evident changes in response to exercise. The values represent median ones

In all the subjects examined there was a clear-cut trend to hypercoagulability in the blood samples taken in the post-exercise period. This trend was most obvious in the samples taken immediately after completion of the work when there was, as compared with the pre-exercise values, a statistically significant shortening in the recalcification time (from 106–197 sec to 101–186 sec) with an associated, statistically significant increase in the plasma-levels of Factor V (to 100–200 per cent), Factor VIII (to 120–540 per cent) and 'contact factor' (to 240–1,000 per cent). In the later post-exercise period these hæmostatic indices acted somewhat inconsistently; but signs of hypercoagulability were still present. The recalcification time continued to shorten. The difference between the recalcification time obtained prior to exercise (106–197 sec) and that observed 60 min following completion of the work (84–152 sec) was statistically significant, and the same held true in the case of 'contact activity'. Meanwhile, the levels of Factor V became normalized whereas those of Factor VIII could be either normalized or raised.

The thromboelastographic r-time appeared to shorten in conformity to the decrease in recalcification time, even if no statistical significance could be revealed. In the thromboplastin generation test increased activity was found both in the combination of test subject plasma—normal serum and in that of test subject serum—normal plasma. However, the changes were not equally marked as were those in the levels of Factor VIII and 'contact factor'.

The parameters remaining unaltered were fibrinogen, prothrombin consumption index, Quick thromboplastin time, $P+P$, Factor VII-complex and Factor IX.

The platelet count appeared to be increased in the samples taken immediately after exercise; but in the subsequent post-exercise period a restoration of the count seemed to take place. The changes were not statistically significant, however.

As for the fibrinolytic activities, there was a statistically significant increase in activator activity in the samples obtained immediately after completion of the work. In the period following, the activator activity showed considerable individual variation. Yet in most instances the normal activity-levels were attained 60 min following the completed work. In two individuals, who exhibited the most pronounced elevation in the activator activity, some increase in the plasmin activity occurred. The plasminogen activity remained unchanged.

In evaluating the results obtained one may proceed from the possible sources or error. In the first place, venous stasis, as used in our tests, has been found to cause hypercoagulability (own observations) and increased fibrinolytic activity[13]. Hence it seems possible that a circulatory activation, following the exercise[3,6], accentuated the stasis-dependent changes especially in the first post-exercise samples and thus contributed to the rather marked hæmostatic alterations encountered at this stage. Secondly, it should be noted that in assaying the coagulation factors, the activity of which is reckoned from dilution curves obtained by use of normal plasma, the accuracy of determinations decreases as the measurable activities increase. Because even at the optimum levels of measurability the accuracy of Factor VIII determinations, for example, lies between 60 and 140 per cent of the figures obtained, it is clear that the accuracy of the determinations is relatively unreliable. Thirdly, as regards the changes in coagulation observed, the response of the individuals to a given work load may vary. Moreover, it is known that anxiety, the degree of which in the present tests, for example, may have varied from case to case and even from one experimental stage to another, readily evokes hypercoagulability with a concurrent increase in the fibrinolytic activity[14]. As regards the work recorded here, however, we are justified in concluding that the changes were great and uniform enough to exclude the possibility that they had resulted merely from an interplay of the factors just discussed and that, accordingly, the changes were occasioned mainly by the work performed.

Our observations on the shortening of the recalcification time and the thromboelastographic r-time with the concomitant rise in the levels of Factor V, Factor VIII and 'contact factor' are in keeping with those already published[1–7]. Whether there was an actual rise in all these activities or whether the results could be traced solely to the increased 'contact activity' or to a development of some new, unknown principle of activity, remains unsettled.

The platelet count was slightly and not wholly consistently increased in the samples of blood taken immediately after exercise. According to Wachholder *et al.*[3], the platelet count is restored within a few minutes following muscular work. Since, in our investigations, the time elapsed from the completion of the work to the time of taking the blood sample for platelet counting was some 1–2 min, it is possible that this delay was sufficient to reduce or abolish thrombocytosis. Within about the same time the exercise-induced circulatory activation, by which mechanism the exercise-thrombocytosis has been explained[6], may disappear[3,15].

In the fibrinolytic activities examined the activator activity was found to exhibit a clear-cut increase. Iatridis *et al.*[5] expressed the belief that in exercise it is mainly the activity of lysokinase, that is, of a factor playing an integral part in the generation of the activator activity, that is increased.

FUNCTIONAL VASCULAR FIELDS IN THE PITUITARY STALK OF THE MOUSE

By Dr. W. CURTIS WORTHINGTON, jun.
Medical College of South Carolina, Charleston

THE hypophyseal portal system of blood vessels has been amply demonstrated to be the morphological basis for the functional link between the hypothalamus and the anterior pituitary. The basic essentials of this system are as follows: (1) a set of primary capillaries (primary capillary 'plexus') in the neurohypophysis, particularly the median eminence and neural portion of the stalk; (2) those nerve fibres of the hypothalamico-hypophyseal tracts which have terminations near the primary capillaries; (3) a series of portal trunks connecting the primary 'plexus' with (4) the 'sinusoids' or secondary capillary 'plexus' in the anterior pituitary. There is an abundance of convincing evidence that neurohumoral substances from hypothalamic nerve endings pass by way of this system into the humoral environment of the glandular cells of the anterior lobe. (For recent reviews of the literature on neuroendocrine control of the anterior pituitary see Harris[1] and the Neuroendocrine Symposium, Miami, 1961 [2], and on the vascular anatomy and microcirculation, Worthington[3].)

Although much has been written concerning the morphology and anatomical distribution of these vessels, comparatively little is known of their physiology[4–7], and nothing is known concerning the possibility of functional specialization of separate vessels or groups of vessels within the system. If one considers particularly the primary capillaries, no evidence has been presented which goes beyond the concept of a functionally uniform network acting as a drainage unit for substances released from nerve endings. Implicit in most discussions of the role of the primary capillaries in the system is the conclusion that this capillary bed is functionally uniform throughout and the vessels freely anastomotic. There is little evidence indicating that there might be functional localization within this capillary bed.

It seems beyond question that the hypophyseal portal system taken as a whole is functionally unique and highly specialized. It also seems possible that specialization occurs within its major sub-divisions. The anatomical evidence concerning the primary capillary system is quite suggestive. The mouse shows an arrangement of groups of capillaries difficult to discern in injected or sectioned material but clear enough if the living stalk and median eminence are examined carefully, which suggests some degree of specialization. In man the vascular tufts and 'glomerular' formations which have been found in injected specimens suggest areas of specialized function[8–11]. Since there is now evidence that more than one substance is released into the primary capillary system for delivery to the sinusoids of the anterior lobe[12–14], and since there is no evidence to indicate whether or not parts of the median eminence and stalk are carrying out special functions, it seemed desirable to determine whether or not there are in the primary capillary area delimited vascular fields which might be functionally separable.

An investigation of this question was carried out by applying a phenomenon which was observed many years ago but has received little attention in recent times. In dead animals the neurohypophysis is intensely stained when injected with methylene blue in dilute solution. This was first described by Dandy[15] in 1913 and was discussed briefly by Bucy[16] in 1930, but seems to have been neglected since. The hypophyseal stalk can also be stained intensely in the living mouse.

In excess of 40 mice were used in this series of studies. The ventral surface of the pituitary stalk and median eminence and portions of the hypothalamus and anterior lobe were prepared under intraperitoneal sodium pentobarbital anæsthesia for direct microscopic observation by a procedure previously reported[4,5]. In brief, this consists of the careful exposure of the structures already described using a ventral approach through the neck. The pharynx, trachea and œsophagus are moved aside and a dental drill is used to make a window in the basisphenoid bone.

The pituitary stalks which have been studied in this series were examined either without further procedures or after the insertion of a small cannula (fashioned from a 30-gauge needle and a piece of *P.E.* 10 polyethylene tubing) into the femoral vein for the administration of a 1 per cent solution of methylene blue.

Observations were made with a Zeiss dissecting microscope giving magnifications of up to 40 times or a Bausch and Lomb binocular compound microscope equipped with 10× or 15× eyepieces and a 10× objective. Effective magnifications of 150 times are attainable with the latter, and resolution is much better than with the dissecting microscope. The Zeiss microscope has a built-in illuminator. A special lamp fitted with two infra-red absorbing filters was used for incident illumination with the compound microscope. In some of the early observations a Leitz Greenough binocular dissecting microscope was used rather than the Zeiss.

Of the more than 40 animals used for this work, 20 were subjected to the interruption of one or more arterial vessels to the median eminence or stalk. This procedure was carried out in the following manner: using number 000 insect pins as dissecting instruments, a very small hole was placed in the transparent dura mater in the vicinity of the blood vessel which had been chosen for

interruption. A second insect pin with a small hook at the tip (made by tapping the pin's point gently on a hard surface) was used to cut the vessel by placing the hook around it and lifting. On occasion sufficient bleeding was caused by this procedure to require that the animal be discarded, but this was unusual. Usually there was sufficient contraction and retraction of the cut tip that bleeding was either absent or minimal. The animals were prepared as outlined either with or without the interruption of small blood vessels and were then injected with from 0·01 to 0·02 c.c./g of body-weight of 1 per cent solution of polychrome methylene blue. Occasionally toluidine blue was used, but it seemed to offer no particular advantage. Observations were made before, during and following the administration of the dye.

General observations and the initial appearance of the dye in the neurohypophyseal tissues in intact animals. Very soon after the beginning of the injection, the dye appears as a very thin, barely detectable, blue line immediately adjacent to some of the capillaries in the median eminence and stalk. Since the dye does not appear in all areas of the visible portions of the neurohypophyseal tissue at the same time, or in the same initial concentration, staining appears at first to be patchy and irregular. As the injection proceeds, the initial thin blue lines take on a deeper colour, gradually take on a granular appearance, and finally fill all the tissue between the capillaries. Finally, after the injection of a total dose of 0·01–0·02 c.c./g of body-weight, the stalk and median eminence are usually uniformly stained. If an area appears to be unstained or considerably more lightly stained than adjacent areas in an animal in which no deliberate cutting of the arterial vessels has taken place such an area has always been observed to have a reduced rate of blood flow in the capillaries. Animals in which several areas of markedly reduced flow were observed before the injection of methylene blue were seldom used for interruption of blood vessels although they can be mapped and their relation to the areas which are affected by manipulation can be determined (Fig. 2).

With the concentration of dye used, the neurohypophysis is the only part of the area under observation which is fairly intensely stained. The surrounding hypothalamic tissue is unstained to all practical purposes, and a small amount of the dye may be found along the anterior edge of the anterior lobe. The continued injection of dye in excess of the dose described above gives a gradually deepening colour to the median eminence and stalk; the neurohypophyseal area becomes blue-black, and the anterior margins of the anterior lobe become considerably more heavily stained. The effect of excess amounts of dye solution given intravenously is finally to interfere with the circulation in the hypophyseal portal system. The capillaries become clogged, and the portal blood flow slows over a period of time and finally stops with the only remaining detectable blood flow occurring in the larger arterial vessels around the stalk. An excessive dose of methylene blue was not routinely given.

If the injection of the dye is discontinued and the stained area observed for a period of time thereafter there is gradual fading of the blue colour. Whether this is due to a diffusion of the dye out of the stalk or the breakdown of the dye to a colourless form is not known. Evidently some diffusion of the dye takes place, but this does not occur so rapidly that small well-delineated vascular areas in the stalk cannot be observed by this technique.

Observation on excised specimens of hypothalamus and neurohypophysis following dye injections. In order to determine something of the more precise localization of the dye in the neurohypophyseal tissue, some specimens were excised following injection of varying amounts of the dye. These were observed *in vitro* with a water immersion lens without the application of a cover slip in order to maintain the dye in the oxidized (coloured) state. The information which has been derived from such observations is primarily negative. Very little can be determined about the nature of the dye and its distribution since, after the tissue has been excised, there is apparently acceleration of the diffusion process. In the living animal the dye appears granular at the levels of magnification obtainable (100–150 times). It also appears to lie rather superficially in the median eminence and stalk between the capillaries. So far it has been impossible to devise a method for obtaining a sufficiently well-preserved cross-section of the unfixed stalk to be able to describe accurately the localization of the dye in the deeper regions. The significant negative observation is that in no specimen that we have examined (either those described in this article or others) have we seen any staining of the small unmyelinated nerve fibres of the hypothalamico-hypophyseal tracts by methylene blue.

This negative evidence is strengthened considerably by the fact that in many of our preparations we have seen numbers of irregularly distributed nerve fibres in the hypothalamus as well as in and just behind the optic chiasma which are very dramatically stained by methylene blue. Occasionally I have seen fibres which are presumed to be vasomotor fibres passing along the courses of the hypophyseal and hypothalamic arteries and on numbers of occasions nerve fibres lying superficially in the hypothalamus (which must be either within the pia or immediately sub-pial) were seen passing into the median eminence and stalk. This was quite dramatically demonstrated when small blood vessels to the primary capillary plexus were interrupted leaving an unstained area in the middle of the stalk. One or two nerve fibres could be seen standing out against a light background. It should be emphaized that these fibres are not the well-organized fibres of the hypothalamico-hypophyseal tracts which stain with silver stains.

Interruption of arterial vessels of the median eminence and stalk. The arterial vessels around the median eminence and stalk and portions of the hypothalamus as they appear in the living animal have been described previously[4,5]. An excellent recent description of injected material has been given by Enemar[17]. The courses of the vessels will not be described in further detail here except where such a description relates directly to the delineation of vascular fields by the methylene blue technique. The result of cutting a small arteriole to the median eminence is shown in Fig. 1. Little or no dye appears in a small fairly well-delineated field. It must be emphasized at the outset that there is no vascular stasis in this small field. Blood continues to flow through the capillaries but at a markedly reduced rate when compared with other capillaries outside of the field. The line of demarcation between stained and unstained tissue is usually quite sharp and falls between capillaries of separate groups. Since no other direct arteriolar supply to this small unstained area can be observed, it is deduced that a reduced capillary blood flow in the area is maintained by anastomoses with surrounding capillaries[4]. It is not impossible that even smaller areas than that shown in Fig. 1 might be affected by this procedure if there were not a limit on the size and location of arteriole which may be interrupted by freehand methods. A larger area of involvement is demonstrated in Fig. 2 after the interruption of a more proximal arterial vessel. Animals in which vessels were removed from one side of the stalk and median eminence are illustrated in Fig. 3. The demarcation between the stained and unstained areas roughly bisect the stalk.

Our experiments using this method suggest very strongly that the blood supply of the upper part of the stalk and median eminence are relatively independent of that of the lower stalk. The lower stalk must have its arterial supply intact to receive dye from the general circulation in sufficient concentration for it to appear in the tissue. The result of interrupting vessels to the upper and lower stalk

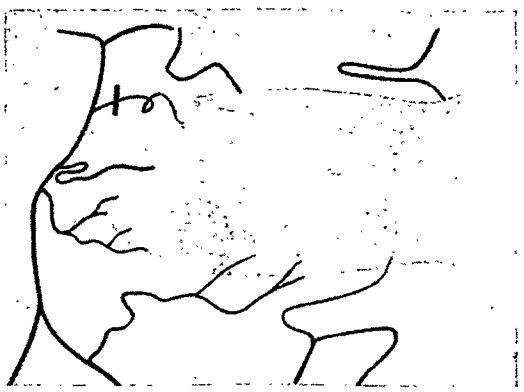

Fig. 1. Arteries and arterioles of the median eminence and stalk of the living mouse. The shaded area outlines the area of distribution of methylene blue in this region. The bar indicates the point at which an arteriole has been cut and the light area, the field in which no dye appeared although blood continued to flow through its capillary bed at a reduced rate. Artist's diagram from author's sketch of the living preparation

Fig. 2. Similar preparation to Fig. 1. More proximal branch of an artery cut as indicated by the bar. There is a much larger area of involvement. The blood flowed at a reduced rate through much of the lighter stained area. The oval area in the upper left part of the diagram represents a less well-stained area in which there was reduced blood flow before cutting stalk vessels

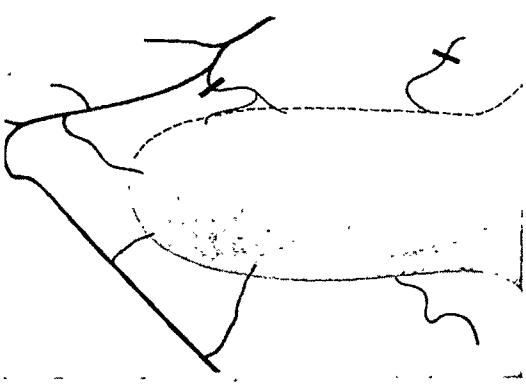

Fig. 3. Interruption of arteries of the left side of the median eminence and stalk

is illustrated in Figs. 4 and 5. The lower lateral margins of the stalk show no dye concentration after cutting the vessel on either side supplying this area (Fig. 4). If the reverse procedure is carried out and these vessels are left intact and others in the upper part of the stalk cut, something of the reverse of this picture is observed (Fig. 5). When only the vessels in the lower part of the stalk (sometimes only a single vessel) are left intact and all the other vessels of the upper stalk and median eminence are cut, one observes considerably more interference with the circulation in the primary capillary system and portal trunks from the upper stalk and median eminence than when some of the vessels in the upper part of the stalk are left intact. Under the former conditions one may see stasis in primary capillaries and in one or more portal vessels. Fig. 6 illustrates the stalk of an animal in which all the hypophyseal arterial vessels in the region had been cut except one which was partially closed as a result of mechanical manipulation. Those areas which are stained still showed fairly rapid flow in the capillaries.

The dye, in order to reach the tissues in sufficient concentration to become visible, must arrive there by way of the arterial vessels and not by capillary anastomoses from the upper part of the stalk and median eminence or by diffusion through the walls of portal trunks. In prepara-

Fig. 4. Interruption of arteries to lower lateral areas of the stalk. Vessels to the upper stalk and median eminence intact

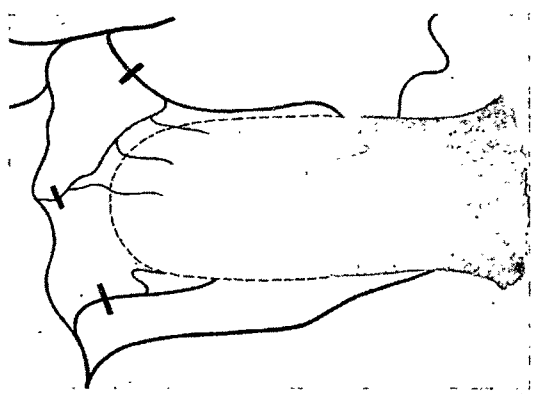

Fig. 5. Interruption of arteries and arterioles to the upper stalk and median eminence. Vessels to lower stalk intact

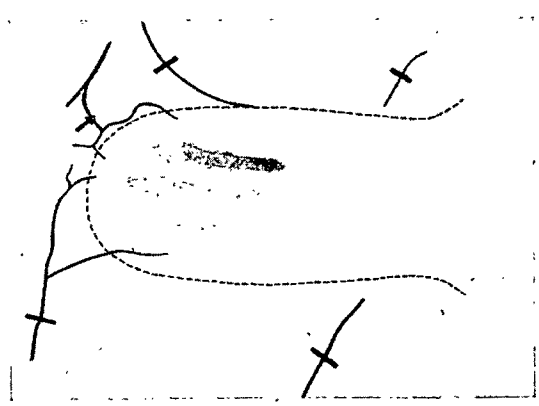

Fig. 6. All vessels to stalk and median eminence cut except that indicated by the arrow. The latter had been manipulated and was constricted, but rapid blood flow was still present. Fairly rapid capillary blood flow remained in the stained areas

tions in which a portal trunk traversed a lightly stained or unstained area the arterial supply of which was cut, no dye appeared in the area although both capillary anastomoses and the portal trunk passed from stained to unstained areas. Occasionally dye appears in an area from which we feel that we have removed the arterial supply or conversely a light area appears but no direct interference with the arterial supply has occurred.

These cases are infrequent. When it is a lighter area which was not anticipated (Fig. 2) there is always a reduced blood flow in this area. Whether this reduced flow is due to arteriolar constriction and reduction in rate of blood flow by physiologic mechanisms or through some incidental and unnoticed trauma during the procedure is not known. In the case of the appearance of dye in an area in which we thought we had removed the arteriolar supply, I afterwards found an arteriole coming from another area, or an intact arteriole closely following the course of the one which had been cut (Fig. 7). Rarely, dye was found in an area in which no arteriolar supply could be demonstrated. These are assumed to receive their supply from the lower stalk blood supply through the under surface. For reasons which should be obvious any animals showing even the slightest sign of trauma directly to the primary capillary system, portal vessels or their arterial supply were discarded and no dye injection investigations were made.

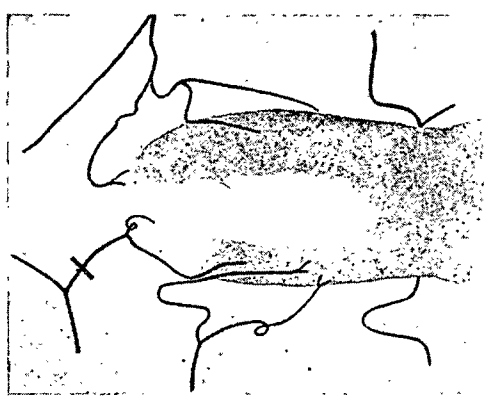

Fig. 7. Dye appears in an area which is served by an arteriole which has been cut. An intact arteriole passes very close to the cut vessel along part of its course

Preliminary observations on differences in dye concentration in animals in different physiological states. There is a distinct difference between pregnant animals and non-pregnant female or male animals in the amount of dye taken up by the pituitary stalk. In the pregnant female comparatively small amounts of the dye injected into the femoral vein impart an intense blue-black colour to the neurohypophysis much more rapidly than one finds in the non-pregnant female and the male animal. This is an incidental observation and thus far no intensive investigation has been made of it.

Discussion

The intense blue colour imparted by methylene blue to the neurohypophysis was observed by Dandy[15] in 1913 and may have been known earlier although he makes no reference to previous observations. Dandy's primary purpose was an investigation of the vasomotor nerve fibres accompanying the blood vessels and he quite correctly stated that he saw no staining of nerve fibres or tracts within the neurohypophysis other than those fibres accompanying blood vessels on their way to the anterior pituitary. The statement by Bucy[16] that it had become apparent since Dandy's work that the intense blue colour of the neurohypophysis is due to the presence of the many unmyelinated nerve fibres which are present is not supported by the observations reported in this article. In none of these were we able to find staining of the hypothalamico–hypophyseal tracts, even in the presence of staining of other hypothalamic nerve fibres. This leaves the nature of the methylene blue staining of the neurohypophysis unresolved. A number of conjectures may be made concerning this matter. The first of these is that the blue colour in the stalk is due entirely to the presence of precipitated methylene blue and that its presence here in higher concentrations than in surrounding brain tissue or in the anterior lobe is due to some fundamental difference in the permeability of the capillary or sinusoidal walls to methylene blue.

The second possibility is that there is some substance which either maintains the methylene blue in the oxidized state more readily in the neurohypophysis, or, conversely, some material which keeps the methylene blue in a reduced state in the surrounding brain tissue and the adenohypophysis. That there is present in the neurohypophysis a substance which maintains the dye in the oxidized state is doubtful. When these pituitary stalks are placed under cover-slips the oxygen is very rapidly used up and fading very rapidly occurs. The colour can be restored to the tissues when the cover-slip is removed and the tissue is allowed to come in contact with the air. In this connexion it may be conjectured that the interruption of the small blood vessels constituting the arterial supply to localized areas of the stalk is not actually reducing the concentration of the dye arriving at these limited areas of the stalk but merely reducing the oxygen tension to the point where the dye is not being maintained in the oxidized state. This latter interpretation is unlikely since the tissues in this region of the mouse are extremely thin and they should receive a supply of oxygen from the air, which is adequate for maintaining the blue colour. The previously mentioned fact that the dye is very rapidly reduced when one of the specimens is placed under a cover-slip would also make the latter explanation unlikely. In either case, however, this method is effective in establishing the presence of fairly well-delineated areas of vascular supply in the neurohypophysis.

Still another possibility concerning the nature of the staining reaction is that there is a specific affinity for some material in the neurohypophysis for the methylene blue. The first material which should be considered is neurosecretory material in the classic Scharrer sense[18]. This seems unlikely since there is a marked discrepancy between the amount of neurosecretory material which occurs in the mouse neurohypophysis stained with the chrome–alum hæmatoxylin technique, and the amount of methylene blue stained material which appears there in the living animal. The former is very sparse[19,20], the latter very heavy. These considerations still do not eliminate the possibility that this stained substance might be neurosecretory material since methylene blue may stain some part of the molecule of this material which does not stain by the chrome–alum hæmatoxylin and might in fact be a better stain for neurosecretory material in the mouse than chrome–alum hæmatoxylin.

These studies with methylene blue have a direct bearing on several aspects of pituitary stalk, neurohypophyseal, and hypophyseal portal function. The unmodified view that the primary capillary plexus is specialized in function only by virtue of location and vascular connexions pervades the literature on pituitary–hypothalamic relationships. Anatomical evidence for distinct groupings of capillaries in man and mouse was mentioned in the introductory paragraphs of this report.

The experiments reported here show that the pituitary stalk and median eminence can be sub-divided, on a vascular basis, into various areas which are functionally separate although there are capillary anastomoses between them. A sufficient rate of perfusion of blood through the capillaries of these areas by way of arterioles must be maintained for a uniform concentration of methylene blue in the blood to diffuse into the neurohypophyseal tissue. It is not an unreasonable hypothesis that this

might be true of other materials as well. These experiments show further that the upper and lower parts of the stalk have a relatively independent vascular supply.

The demonstration of more than one adenohypophyseal trophic factor from the hypothalamus[11–13] leads one to the question whether these materials are being released uniformly throughout the median eminence and stalk, or whether, alternatively, certain functions are located in separate areas of the stalk. One may ask further, whether the rate of release of these materials is governed completely by some functional attribute of the neuron or neuron terminals from which they are released or whether variations in the rate of blood flow through independent vascular fields contributes something to the rate of delivery of these materials into the portal trunks and thence into the adenohypophysis.

Although any conclusion on these matters at the present time would be premature, the experiments reported here demonstrate that such functional areas could exist and could be controlled in some measure by vasomotor control of blood flow into a given area. Experiments demonstrating chronic insufficiency of specific stalk-mediated functions by interrupting vessels to specific areas and maintaining the animals for long periods of time have been attempted. They have all so far failed because animals have not survived the experiment. The factors involved are not entirely clear although it does not involve the interruption of hypothalamic blood vessels or damage to the hypothalamus or to the pituitary stalk. Sham-operated animals with no manipulation of stalk vessels or hypothalamic damage also failed to survive.

The second major point which these experiments demostrate is that 'titre' or concentration of material in the circulating blood is not the only factor controlling the rate at which materials can arrive in the median eminence and stalk or in the anterior lobe.

It is obvious from these experiments that rate of capillary blood flow markedly influences the ability of the neurohypophysis to take up and concentrate the dye methylene blue. In every case where there were lighter areas of the stalk after injection of the dye there was a reduced blood flow rate. It can be concluded that there was a sufficient concentration of the dye in the blood of the stalk capillaries flowing at a rate insufficient to bring about a visible accumulation in the tissues.

In summary, these experiments with a dye which diffuses readily from primary capillaries into the neurohypophyseal tissue lends support to the following hypotheses: (1) That small regions of the pituitary stalk and median eminence are functionally separable on the basis of the arterial supply to different parts of the primary capillary system. (2) That capillary perfusion rate is an important factor in determining the amounts of materials which pass from primary capillaries to neurohypophyseal tissue. (3) That the arterial blood supply to the upper stalk and median eminence is functionally relatively independent of the lower stalk. (4) That the permeability of the primary capillaries varies with physiological state. It is possible that all these factors are involved in the fine control of pituitary function by hypothalamic neurohumours and/or materials from the general circulation.

ZYMOSAN, an insoluble lipoprotein-polysaccharide derived from the cell wall of yeast cells, inactivates the third component of complement[1,2], produces hyperplasia and hyperfunction of the reticuloendothelial system[3–7]. Furthermore, it increases the resistance of mice towards bacterial infections[8] and ionizing radiation[9]. It enhances the formation of antibody[5] and also prevents the development of tumours[10] in animals and is pyrogenic and antigenic in rabbit[11].

This article describes a method for producing from zymosan a water-soluble polypeptide. This material protects, after intraperitoneal injection, mice against *E. coli* infection. Furthermore, it diminishes the lesion produced by vaccinia virus in rabbit skin. It also provides some protection of chick embryo against vaccinia virus. Finally, in tissue culture it inhibits the mitotic activity of HeLa cells.

2 g of commercial zymosan (from fresh yeast, type *A*, L. Light and Co., Colnbrook, England) prepared from Fleischmann yeast was extracted at 37° C with 150 ml. of 90 per cent aqueous phenol for 2 days. Undissolved material was removed by centrifuging and the clear

supernatant was shaken with 750 ml. of ether and 500 ml. of water. The aqueous phase containing a suspension of precipitated material was re-extracted with ether to remove phenol and the precipitate subsequently brought into solution by adjusting the *p*H to 9. The solution was concentrated in vacuum to a small volume and passed through a 'Sephadex *G* 50' (40 cm high × 4 cm diam.) column previously equilibrated with 0·01 N sodium hydroxide. The high molecular fraction was collected, neutralized with 'Amberlite *IR* 120 (H)' to *p*H 7·0 and freeze-dried. 0·07 g of a white solid was obtained. To purify it further, the white solid was dissolved in water (50 ml.) and centrifuged at 20,000*g*. To the clear supernatant was added 2 ml. of 20 per cent of sulphosalicylic acid, the precipitate redissolved in water by adjusting *p*H to 7 with sodium hydroxide, dialysed at +4° C against distilled water for 24 h and freeze-dried.

It is seen from Table 1 that the material is largely a polypeptide and contains only small amounts of carbohydrate. 'Sephadex *G* 50' excludes material with molecular weight equal or greater than 8,000–10,000. These figures could therefore represent a lower limit for the molecular weight of the polypeptide. It is precipitated on acidification and by sulphosalicylic acid, phosphotungstic acid and ammonium sulphate (completely precipitated at 50 per cent saturation).

Table 1. Analytical Results of the Material Prepared from Zymosan

	Per cent
Nitrogen*	12·69
Biuret†	92·0
Hexose content‡	1·9
Hexosamin content §	0

* Material dried at 105° C over P_2O_5 and analysed by the Dumas method. Bovine serum albumin by the same method gave 14·8 per cent (carried out by Dr. A. Schoeller, Kronach).
† The Biuret method of Gornall *et al.* (ref. 12) was used. The figure given is in percentage of the colour produced by an equal amount of serum albumin.
‡ The anthrone method of Goa (ref. 13) was used.
§ The modified Morgan–Elson method of Svennerholm (ref. 14) was used.

On electrophoresis in veronal buffer at *p*H 8·6 (ionic strength 0·1) on Whatman No. 1 followed by staining with Amido-Schwarz, the main part of the stainable material is negatively charged and moves as a homogeneous band. The distance travelled is 35 per cent of that travelled by bovine serum albumin.

Hydrolysis in 6 N hydrochloric acid at 110° for 20 h, followed by two-dimensional chromatography in *n*-butanol–acetic acid–water (200 : 48 : 200) and *n*-butanol–methylethylketone–water (200 : 200 : 1) in *cyc*lohexylamine, revealed the presence of glutamic acid, aspartic acid, arginine, lysine, histidine, glycine, serine, proline, alanine, valine, tyrosine, threonine, phenylalanine, leucine and isoleucine.

The ultra-violet absorption spectrum at *p*H 7·0 in *tris*-hydrochloric acid is seen in Fig. 1.

An aqueous solution of the material exhibits in the ultra-violet light a bluish fluorescence.

Pyrogenicity. 1 mg of the material was dissolved in 1 ml. of saline and injected intravenously into each of four rabbits and the temperature recorded as described previously[15] over a 3-h period. The maximum increase in temperature in each of the four rabbits respectively was 0·4°, 0·4°, 0·5°, 0·6° C, and shows that the material was not pyrogenic at this dose level.

Bacterial challenge. The effect of the intraperitoneal injection of 50 μg of material prior to the intraperitoneal

Table 2. Effect of the Material Isolated from Zymosan on *E. coli* Challenge in Mice

Hours between injection of material and bacterial challenge	Survivors/total mice in experiment
3	11/18
6	11/18
24	8/18
Controls	2/18

0·1 ml. pyrogen-free saline containing 50 μg of material was injected intraperitoneally into Swiss albino mice weighing about 20 g. The mice, including the controls, were challenged intraperitoneally with 0·25 ml. of a suspension of 1·25 × 10^8 *E. coli* grown and prepared as described previously (ref. 15).

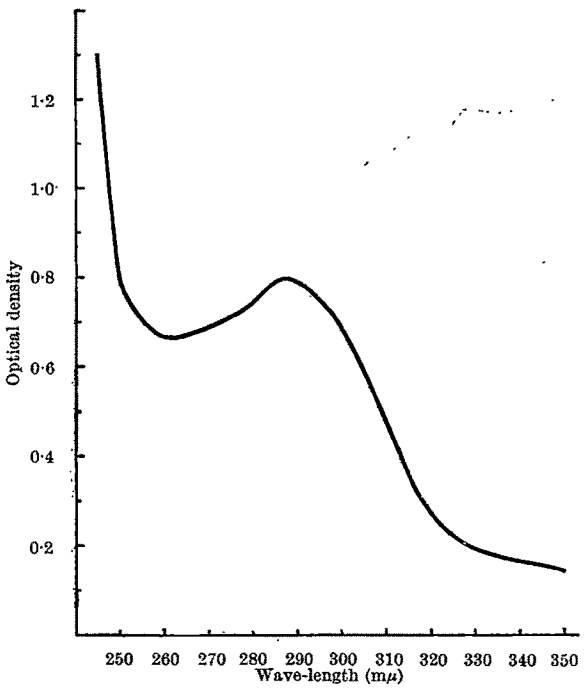

Fig. 1. The ultra-violet absorption spectrum of material prepared from zymosan in *tris*-hydrochloric acid buffer 0·1 M, *p*H 7·0 (0·33 mg/ml.)

injection of *E. coli* in mice is seen in Table 2. It is apparent that the material offers some protection against the bacterial challenge.

Vaccinia virus in rabbit skin. The effect of different quantities of material injected intracutaneously into rabbit skin prior to infection (on the same site) with vaccinia virus is seen in Table 3. It is apparent that the material reduces the development of lesions.

Vaccinia virus in chick embryo. The result of administering the material to chick embryo 24 h prior to infection with vaccinia virus is shown in Table 4. It is seen that the material provides some protection of chick embryo against vaccinia virus.

Mitotic activity in HeLa cells. The effect of the material on the mitotic activity of HeLa cells grown in the *E2a* medium of Puck, Cieciura and Fisher[16] is seen in Fig. 2. It is apparent that 0·33 mg/ml. reduces the mitotic index

Table 3. Effect of the Material Prepared from Zymosan on the Development of Vaccinia Virus in Rabbit Skin

Amount of material injected (μg)	Area free of lesions	
	Rabbit 1	Rabbit 2
400	1 cm × 0·5 cm	0·5 cm × 0·5 cm
200	0·5 cm × 0·3 cm	1 cm × 0·5 cm
100	No area free of lesions	No area free of lesions
Controls	No area free of lesions	No area free of lesions

White land rabbits weighing 3–4 kg were used. The animals were epilated with barium sulphide on the flanks. 0·2 ml. of a sterile saline solution of the material was injected intracutaneously (0·2 ml. saline as control), the area at and around the injection site scarified (ref. 15) and a solution of vaccinia virus applied to the area. The vaccinia virus used was a vaccine prepared from chick embryo infected with vaccinia virus and was free of bacteria. The results were recorded after 10 days.

Table 4. Effect of the Material Prepared from Zymosan on Chick Embryo Infected with Vaccinia Virus

Exp. No.	Amounts of material administered to each embryo (μg)	Survivors/total embryos	
1	2	23/37	
	controls	3/35	
2	10	5/5	Total 20/20
	5	5/5	
	2·5	5/5	
	1·0	5/5	
	controls	4/10	

Eggs from White Leghorn were used. After 10 days at 37° a 0·5 cm × 0·5 cm window was drilled over the chorio-allantoic membrane and the membrane dropped by suction over the air sack. 0·05 ml. of a sterile solution in saline of the material to be tested was applied to the membrane. 0·2 ml. of a vaccine (free of bacteria) prepared from a cell culture of calf embryo epithelial cells infected with vaccinia virus (ref. 15) was applied on the same spot after 24 h at 37°. The window was sealed with cellophane tape, eggs incubated for 4 days and deaths determined.

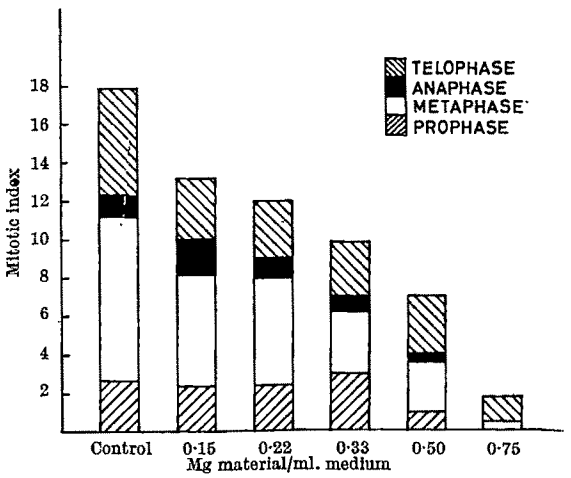

Fig. 2. The effect of the material prepared from zymosan on the mitotic index of HeLa cells
HeLa cells strain *S3* were grown in tubes as a monolayer on glass plates in *E2a* medium at 37°. The control is the average of the results from 10 tubes and the experiments the average of results from five tubes. The mitotic index was determined after 24 h exposure to the material. For further details of the experimental technique see Oftebro, Laland, Dedichen, Laland and Thorsdalen (ref. 17)

the HeLa cells with 50 per cent. Furthermore, the results suggest that the material interferes with some processes in the interphase. No chromosomal abnormalities were seen.

The experiments described here demonstrate that a high molecular polypeptide can be extracted from zymosan. This is rather surprising since the preparation of zymosan involves exhaustive digestion with trypsin[1].

The polypeptide material prepared from zymosan resembles in its biological properties material isolated from liver and blood and described previously[15]. These latter materials are, as the zymosan material, essentially polypeptides[16]. However, they differ from the zymosan material in being more soluble at acid *p*H. They are similar so far as they all exhibit in aqueous solution a bluish fluorescence in ultra-violet light. It is tempting to speculate that the fluorescent substance is required for biological activity and that this substance is the same or a closely related substance to those present in the materials prepared from liver and blood.

The reported biological properties of the polypeptide material prepared from zymosan indicate that it increases the resistance of the animal both against bacterial and viral challenge. It is thought that this might be caused by a general cellular effect. The effect on the mitotic activity of HeLa cells provides an example of the cellular effect of the material on one particular kind of cells.

The substance in zymosan responsible for its biological properties is still a question of disagreement. Heller[19] reported to have isolated from zymosan a non-toxic lipid which stimulated the reticuloendothelial system whereas Riggi and di Luzio[20] claim that the glucan part of zymosan is responsible for the stimulation of the reticuloendothelial system. Whether or not the water-soluble polypeptide prepared from zymosan and described in this paper is responsible for all the biological properties of zymosan cannot be concluded from the present experiment.

ELECTRON-DONOR OR ELECTRON-ACCEPTOR PROPERTIES AND CARCINOGENIC ACTIVITY OF ORGANIC MOLECULES

THE possible correlation between the electron-donor or -acceptor capacities of aromatic molecules (as exemplified by their ionization or reduction potentials) and their carcinogenic activity was examined for the first time in 1955 [1]. We concluded that no significant correlation existed between these two types of property although it was pointed out that some restricted correlations between the electron-donor capacity and the ability to produce tumours could be observed in some limited series of active molecules. Recently the problem of the possible involvement of the electron-donor or -acceptor properties of molecules in promoting carcinogenic activity has been raised again by some authors[2–5], and we have already discussed some of these contributions[6,7]. This type of approach seems to have culminated in the very recent paper by Allison and Nash[8], who postulate that "carcinogenicity arises as a result of a suitable combination of *both* electron-donating and electron-accepting properties in a compound". The authors explicitly recognize that neither of these properties alone is sufficient by itself for carcinogenesis, because as they say "many drugs which are apparently not carcinogenic are either donors or acceptors of electrons". They consider that the combination of both electron-donating and electron-accepting properties in the same molecules is, however, rare, and that it is a particular characteristic of carcinogenic compounds.

The erroneous nature of this proposition may be demonstrated in a number of ways. Thus let us consider the aromatic polybenzenoid hydrocarbons, which not only represent one of the most important and largest group of compounds investigated for carcinogenic activity but which are also the most advantageous example, from the point of view of Allison and Nash, because, as is well known from general quantum chemistry, the electron-donor and electron-acceptor properties of these molecules run parallel, so that in this series the same molecules combine these two properties. This situation already destroys one of the arguments of Allison and Nash. In these molecules, at least, the properties of being a good donor and good acceptor always go together and are in no way an exceptional situation. Moreover, it results from this fact that if there is no correlation in this series of molecules between their carcinogenic activity and their electron-donor or their electron-acceptor capacity (and

the authors themselves admit that there is none), there cannot be either any correlation between carcinogenicity and the combination of these two properties.

That this is really the situation is obvious already from an objective examination of the data of Allison and Nash themselves. These authors base their proposition on the results of charge-transfer complex formation of carcinogenic molecules with chloranil and 1,3,5-trinitrobenzene and on the polarographic determination of the electron donating and accepting properties of these molecules. A typical situation for the fundamental unsubstituted hydrocarbons is illustrated in Table 1, extracted from these authors' data, where the energy of the charge-transfer band with chloranil, E_{CT}, is listed against the carcinogenic activity. The electron-donor properties of the hydrocarbons are considered to be the greater, the smaller E_{CT}.

Table 1. CHARGE-TRANSFER FORMATION OF AROMATIC HYDROCARBONS WITH CHLORANIL AND CARCINOGENICITY (Results of Allison and Nash)

Compound	E_{CT} (eV) chloranil	Carcinogenicity
Phenanthrene	2·72	−
Naphthalene	2·64	−
Chrysene	2·52	−
Triphenylene	2·44	−
1,2-Benzpyrene	2·18	−
1,2,7,8-Dibenzanthracene	2·18	+
1,2,5,6-Dibenzanthracene	2·16	+ +
Pyrene	2·13	−
Coronene	2·08	−
1,2-Benzanthracene	2·05	±
Anthracene	1·98	−
1,2,3,4-Dibenzpyrene	1·91	+ +
3,4,9,10-Dibenzpyrene	1·91	+ + +
3,4-Benzpyrene	1·79	+ + +
1,2-Benzperylene	1·85	± (?)
Perylene	1·83	−
3,4,8,9-Dipenzpyrene	1·82	+ + +
Naphthacene	1·67	−

The conclusion which these authors draw from such a table, namely, that as a rule the carcinogenic hydrocarbons are stronger donors than other hydrocarbons, is not justified. Thus, if the value of E_{CT} in 1,2,7,8-dibenzanthracene, a weak carcinogen, is taken as the threshold, six inactive compounds out of ten studied should have been carcinogenic. In fact, such completely inactive compounds like perylene or naphthacene are among the best donors. This situation is so striking that these authors themselves suggest that there must be other factors playing a part and responsible for these 'exceptions'. We shall discuss these other factors later. What must immediately be stressed here is that the real situation is much worse than appearing from the limited data of Table 1. Thus Allison and Nash have examined the majority of the active aromatic hydrocarbons, but only 12 out of the 32 polybenzenoid hydrocarbons known to be non-carcinogenic. Moreover, most of these 12 inactive molecules are of relatively small dimensions (composed of 4 or less fused benzene rings) and have thus *a priori* relatively low electron-donor or -acceptor properties, while the important carcinogens are of a bigger size (composed of 5 or 6 fused benzene rings).

The type of results which Allison and Nash would have obtained had they included in their investigation a larger number of non-carcinogenic molecules of dimensions comparable with those of the strongly carcinogenic ones may already be guessed from the case of naphthacene and perylene in Table 1 and is shown in more detail in Table 2. This last table represents the absolute value $|k|$ of the energy coefficients of the highest filled and the lowest empty molecular orbitals in all the polybenzenoid aromatic hydrocarbons which have been studied for carcinogenic activity. As is well known[9], these coefficients obtained by molecular orbital calculations measure, respectively, the electron-donor and the electron-acceptor properties of molecules and in the particular case of the aromatic hydrocarbons the smaller the coefficient of Table 2, the greater both the electron-donor and the electron-acceptor properties of these molecules. The reliability of these coefficients for the measurement of these properties of aromatic hydrocarbons is substantiated by the available correlations between these coefficients and ionization potentials[9–11], polarographic oxidation potentials[12], electron affinities[9,10], polarographic reduction potentials[13,14] and the wave-length of charge-transfer bands, in particular in complexes with a given acceptor (for example, refs. 15–17).

A glance at Table 2 immediately shows that if such a wider study is made, the correlation postulated by Allison and Nash vanishes completely, the carcinogenic molecules and the related non-carcinogenic ones being indistinguishable from the point of view of their electron-donor or acceptor properties.

Still restricting ourselves to the aromatic hydrocarbons, which means giving the theory of Allison and Nash its best chances, we may also present a more general criticism of their proposition. Thus, proposing that carcinogenesis is dependent on great electron-donor and -acceptor properties of molecules, leads naturally to some general predictions. One of such predictions would be that acenes, which are by far both better electron-donors and better electron-acceptors than the isomeric phenes, should also be better carcinogens. Such a prediction is in complete contradiction with the fundamental facts of carcinogenesis by aromatic molecules, where only phenes are carcinogenic and where even the presence of a small acenic fragment in a molecule is incompatible with activity[18]. Another prediction would be that large hydrocarbons should, in general, be better carcinogens than small ones, the electron-donor and -acceptor properties increasing, as a mean, with molecular size in these conjugated systems. This again is in contradiction with experiment, which shows that the activity is maximum for compounds composed of 5 or 6 fused benzene rings. If steric effects may surely be invoked to explain the inactivity of bigger molecules or of substituted derivatives containing long substituent chains[19], they cannot account for the difference in activity among the hydrocarbons composed of 5 and 6 fused benzene rings, where the active and inactive molecules are frequently of a very comparable size and shape. Finally, a third prediction which may naturally be made on the basis of Allison and Nash's general postulate is that, say, the different methylated derivatives of the same hydrocarbon (for example, the different methylbenzanthracenes) should all behave similarly from the point of view of their carcinogenic

Table 2. ELECTRON-DONOR (OR ACCEPTOR) PROPERTIES OF HYDROCARBONS AS MEASURED BY THE ABSOLUTE VALUE OF THE COEFFICIENT $|k|$ OF THEIR HIGHEST FILLED (OR LOWEST EMPTY) MOLECULAR ORBITAL

Compound	$\|k\|$	Carcinogenicity	Compound	$\|k\|$	Carcinogenicity	Compound	$\|k\|$	Carcinogenicity

1,2,3,4-Dibenzphenanthrene	0·532	+	4,5,10,11-Di(1′,2′-naphtho)-chrysene	0·383	−	Anthanthrene	0·291	−
Chrysene	0·520	−	3,4-Benzpyrene	0·371	+ + +	3,4,9,10-Di(2′,3′-naphtho)-pyrene	0·273	−
Picene	0·501	−	1,2,9,10-Dibenznaphthacene	0·361	−	Pentacene	0·220	−
1,2,3,4-Dibenzanthracene	0·499	−	1′,2′-Anthra-1,2-anthracene	0·360	−	Naphthodianthrene	0·177	−
1,2-Benzpyrene	0·497	−	1,2,7,8-Dibenznaphthacene	0·358	−			
1,2,7,8-Dibenzanthracene	0·492	+						

potency, because they all have rather similar electron-donor or -acceptor properties (a fact verified by the proper results of Allison and Nash). Such a prediction would again be in disagreement with experiment, the monomethylbenzanthracenes ranging from inactive to quite powerful carcinogens.

This last remark brings us to discuss the other groups of molecules quoted by Allison and Nash in support of their theory.

In these cases again there seems to be no contact between the very data presented by these authors and their interpretation of them. Thus Allison and Nash state that their results indicate that the carcinogenic aromatic amines are better electron donors than the non-carcinogenic ones. In fact, nothing of this kind is apparent from their data. They have studied 14 carcinogenic aromatic amines and only 5 non-carcinogenic ones. Even so, not the slightest distinction can be made between the electron-donor properties of these two groups of molecules. The carcinogenic and non-carcinogenic aromatic amines are intertwined in an indistinguishable way. In fact, some of the non-carcinogenic ones are better electron-donors than the carcinogenic ones. The same situation obviously prevails also, as can be seen in the very numerical data given by these authors (and in contrast to their interpretation of them), in the group of heterocyclic-*N*-compounds. Finally, in the groups of steroids the authors observe and consider it significant that only œstrogens, which are the most carcinogenic among the steroids, are relatively good electron-donors. To this it may, however, be objected that they seem to be particularly bad electron acceptors[20]. Now it is the combination of both properties that Allison and Nash consider as important for carcinogenesis. If one of these properties alone is sufficient, this could be equally well electron acceptance, a property particularly outstanding, among the steroids, in the adrenocortical hormones[20]. Moreover, although apparently devoid of electron-donor properties[8] and possessing only moderate electron-acceptor properties[20], the androgens are not without carcinogenic potentialities[21].

It seems therefore obvious that no correlations can be claimed to exist between the carcinogenic activity of organic molecules and their electron-donor or electron-acceptor properties or the combination of both. The results of Allison and Nash, when looked at objectively, preclude the establishment of any such correlations. In the rare cases where some doubts could exist about this situation a study of some supplementary compounds can settle the problem quickly. This state of affairs does not preclude, of course, that some forms of electron-transfer reactions may play a part in the interaction between the carcinogens and their tissue receptors. There is even some evidence that such may be the case[6,22]. The involvement of such a transfer in carcinogenesis is, however, a secondary feature subject to the fulfilment of other primary conditions which, for example, in the aromatic hydrocarbons, are based on the characteristics and probably the reactivities of the *K* and *L* regions[1,18]. Statements, such as the following, found in a recent publication[23]: "Because polynuclear aromatic hydrocarbons are devoid of polar functions, such as —OH or —NH_2 groups, the only possible bonding of such compounds to biological systems is that of charge-transfer complex formation", are entirely unwarranted and ignore the numerous chemical potentialities of such molecules. These molecules undergo many chemical reactions on their *K* and *L* regions or at their reactive carbons and there is no apparent reason why the same active centres should not be involved in their biochemical reactions. The work of Heidelberger *et al.*[24] shows that they are so involved.

One of the temptations which probably induce some authors to develop theories of the type of that proposed by Allison and Nash is that such theories have the apparent attraction of being susceptible to offer a unique concept for the mode of action of the different types of known chemical carcinogens, a pretention which the *K–L* regions theory has not. In this respect it may, however, be remarked that while most probably the final intimate unknown event representing carcinogenesis is common to all carcinogens, it is, on the contrary, quite improbable that a unique type of "a reaction" and thus a unique characteristic could be responsible for the activity of the different types of carcinogens. This conclusion is substantiated by the multitude of different processes by which these different types of molecule may interact with probable cellular receptors such as, for example, the nucleic acids[9,25,26] and also by the results of the recent studies on the mechanism of action of the related mutagens, which show that the molecular event representing a mutation, and which most probably consist of the perturbation of the normal sequence of the complementary base-pairs of the nucleic acids, may be brought about by a variety of different types of reaction occurring between the mutagens and their target, at different sites of the target.

This work was sponsored by Convention No. 61–*FR*–134 of the Délégation Générale à la Recherche Scientifique et Technique (Comité Cancer et Leucémie).

In our papers we were careful not to criticize the Pullmans' work since we believe that it is not only permissible, but desirable, that alternative approaches be tried to the elucidation of carcinogenic mechanisms, about which so little is known. In particular, theoretical and experimental approaches to the physico-chemical problems involved are complementary, and each has something to offer the other. However, the attack which the Pullmans have delivered on our paper compels us to defend our hypothesis and compare it with theirs.

In assessing the Pullmans' arguments it must be borne in mind that the quantum-mechanical calculations they make involve a series of approximations. As Szent-

Gyorgyi has put it[1]: "the k values obtained depend on the parameters used, which may be subject to change. As mentioned before, experience and intuition are needed in this line, which also means that there is no numerical rigidity. Another, even more serious, shortcoming is that the k values of substances belonging to different chemical series cannot be strictly compared, since both α and β [the 'Coulomb integral' and 'exchange integral' of the method] may vary in different chemical series by as much as 25%. If the numerical value of α is around 6 eV, 25% means 1·5 eV, more than the total energy of biological oxidation". It may be added that the differences with which we are concerned seldom exceed 1·5 eV. Thus, what the Pullmans claim to be "measurements" of k values are merely subjective estimates which have some measure of reliability in the case of unsubstituted hydrocarbons (though absolute values for electron-donating or -accepting energies still have to come from experiments), but become progressively more uncertain in substituted and heterocyclic compounds. Fortunately, it is now possible to supplement such estimates with measurements of electron-donating and electron-accepting capacities of aromatic hydrocarbons and other compounds by several methods, which give very similar results. Sometimes these results have been found to differ markedly from those calculated theoretically, for example, in the case of electron acceptance by tropylium and pyridinium ions[2,3] and electron donation by chlorpromazine[4,5]. Hence theoretical calculations are no substitute for experimental results of the kind which we presented.

Our main point is that a wide range of chemical carcinogens, other than alkylating agents, are powerful electron donors and are also electron acceptors. The Pullmans have not attempted to deny this interesting fact. Nor can it be supposed that these properties recur in many other classes of organic compounds. We have been looking for compounds having the right electronic properties, lipid solubility, and stability under physiological conditions, and have found very few; suggestions from readers as to suitable compounds would, in fact, be welcome. However, it is also true, as we were careful to point out, that some compounds related to carcinogens have similar electronic properties but are inactive in biological tests. We offered three explanations why this might be so: first, that steric factors could prevent charge transfer with the relevant biological constituents; secondly, that the electron distribution could be unfavourable for such charge transfer; and thirdly, that the carcinogenic compounds could be more stable and less easily metabolized to inactive products than the non-carcinogenic compounds.

Most of the points raised by the Pullmans were explicitly and fully discussed in our papers, so there is no need to recapitulate the arguments. We find ourselves unable to agree with any of the new points made by the Pullmans:

(1) While it is unquestionably true that examination of unsubstituted polybenzenoid hydrocarbons gives the K–L region hypothesis its greatest chance of success (the calculations being less uncertain than for other compounds), this is by no means true of our hypothesis. Indeed, the whole point of our hypothesis is its applicability to a wide range of compounds of different kinds.

(2) The Pullmans state that electron-donor and electron-acceptor properties increase with increasing size in polycyclic aromatic hydrocarbons. This is by no means true, as our results (and even the k values in their Table 2) show. To take a few examples among many, chrysene (4 rings), pyrene (4 rings), 1,2-benzyprene (5 rings) and coronene (7 rings) are weaker donors than anthracene (3 rings).

(3) According to the Pullmans, in aromatic polybenzenoid hydrocarbons electron-donor and electron-acceptor properties always run in parallel. However, the experimental results presented in Table 1 of our second paper show that in all such compounds tested electron-donating capacity is much greater than electron-accepting capacity. While in the unsubstituted compounds parallelism exists in the sense that stronger donors are also stronger acceptors, this relationship is broken down in substituted compounds, as Streitweiser and Schwager have shown[6]. Our own results demonstrate, for example, that 9,10-dimethyl-1,2-benzanthracene is a stronger donor but a weaker acceptor than 1,2,5,6-dibenzanthracene. We found monomethyl-benzanthracenes to have very similar electron-donating capacities, but in measurements of electron-accepting capacity Pointeau[7] has found differences from which he concludes: "On constate immediatement qu'a l'exception du 5-Me et pour les deux premières vagues, les composés les plus concérigènes possèdent des potentiels de réduction plus bas que les autres".

(4) The Pullmans concede that steric effects can be invoked to explain the inactivity of the large hydrocarbons and of derivatives containing long substituent chains. This, incidentally, removes several of the compounds with low k values from their Table 2. However, the Pullmans feel that steric factors cannot account for differences in carcinogenicity of methyl-derivatives of 1,2-benzanthracene, or among hydrocarbons composed of 5 or 6 fused benzene rings "where the active and inactive molecules are frequently of a very comparable size and shape". In other words, substitution of a methyl group here or there, or even a benzene ring here or there, makes very little difference to the shape of a molecule. Such statements seem to have little contact with chemical or biological reality. Numerous examples could be quoted of small substitutions in hormones or drugs having profound effects on biological activity. With carcinogens there is somewhat greater latitude for modification, but obviously this has limits. Although Huggins and Yang's[8] frame must be deepened in order to accommodate 9,10-dimethyl-1,2-benzanthracene and œstrogenic steroids, which are non-planar, it serves to remind us that only certain configurations are permissible in carcinogens, which might have been expected *a priori*. Many non-carcinogenic hydrocarbons with low k values might be excluded on this basis alone.

(5) The Pullmans overlook our argument about the stability of hydrocarbons under physiological conditions. As we mentioned, polarographic experiments show an interesting feature that could not have been predicted theoretically, namely, that in some series of compounds, only carcinogens were found to undergo single-electron oxidation. This is true of 3,4-benzpyrene (using the classical terminology) whereas pyrene itself was oxidized by a two-electron step and 1,2-benzpyrene by a three-electron step, with the formation of insoluble products. Anthracene and 1,2-benzanthracene undergo multi-electron oxidation whereas carcinogenic benzanthracene derivatives do not. Thus the products of oxidation of carcinogens are likely to be more stable than those of non-carcinogens. Other such differences were found among amines and will be discussed elsewhere. With regard to acenes, we are not aware of any experiments showing that they are "far better electron donors and electron acceptors than the isomeric phenes" but if this is so it is highly improbable that they would be stable in the body.

(6) The Pullmans apparently agree with our statement that among steroids only œstrogens are strong electron donors, but they ignore our experimental results showing that solvated œstrogens (including stilbœstrol) are easily measurable electron acceptors. As we said, the only steroids that are efficient carcinogens are œstrogens, which reproducibly induce tumours in a variety of experimental situations[9]. This is certainly not true of the androgens[9]. The alleged carcinogenic effects of testosterone in the paper quoted by the Pullmans[10] are based on trivial differences from controls which do not even approach statistical significance at the 5 per cent level. If the androgens are carcinogenic at all, the fact that high doses were used for

long periods makes it difficult to exclude the possibility that the small effects observed are due to metabolites.

(7) The Pullmans' statement about heterocyclic *N*-compounds seems to arise from their failure to appreciate that such compounds, and also amines, are better electron donors as measured polarographically than is evident from charge-transfer absorption spectra (Fig. 1 and Tables). We can only repeat that the carcinogenic dimethylbenzacridine was a stronger electron donor than the non-carcinogenic acridine and benzacridine, and that the highly carcinogenic benzpyridocarbazoles were among the strongest donors in all the compounds tested (Table 1 of the second paper). Although carbazole was also a strong donor, it had no measurable acceptor property and is in any case known to be rapidly metabolized. The case of indole, also a strong donor, illustrates the difficulties that can arise when attempting to make any simple comparison of chemical and biological properties. The experiments of Ehrhart *et al.*[11] demonstrate at an acceptable level of significance the carcinogenicity of indole. However, since certain metabolites of indole, notably 3-hydroxy-anthranilic acid, are themselves carcinogenic, they might be responsible for the effects observed with indole itself. Some amines are activated by metabolic changes such as *N*-hydroxylation, and inactivated by other metabolic changes. Hence rejection of our hypothesis out of hand because the *prima facie* correlations between electronic properties and carcinogenicity are imperfect shows lack of appreciation of the complexity of the biological situation.

(8) We believe that our hypothesis was well worth developing. The Pullmans merely recapitulate what they have already written many times. There are difficulties about the *K–L* region hypothesis (for example, the difference in carcinogenicity of 3- and 4-fluoro-substituted 10-methyl-1,2-benzanthracenes[12]) which seem to imply that it requires still further qualification. There is danger in stagnation; we have attempted to let in some fresh air. Others had previously considered separately the electron-donating and electron-accepting properties of certain carcinogens. We showed that this view could be generalized to bring out common features in carcinogens of very different chemical structure (hydrocarbons, steroids, aromatic amines and heterocyclic *N*-compounds). We believe that our hypothesis is more useful than the Pullmans' because it is at once more specific and more general: more specific because it is based on particular and objectively measurable properties of molecules and not mathematical abstractions; and more general because it is applicable without any *ad hoc* assumptions to a wide range of compounds. Furthermore, our hypothesis has greater predictive value, both in suggesting new carcinogens and in suggesting specific possibilities as to modes of action rather than the "numerous chemical potentialities of the *k* region" which the Pullmans seem unwilling to specify more precisely. Our hypothesis could change the emphasis of research in this field. Until now it has been customary to examine molecules to ascertain what makes them carcinogenic. We think that the problem should be reversed, examining other compounds with the right electronic properties in order to ascertain why they are not carcinogenic: and this suggests numerous experiments.

(9) The Pullmans criticize us for attempting to offer a unique concept for the mode of action of different types of chemical carcinogens. They fail to notice that we explicitly excluded alkylating agents, so that in fact we offered two independent carcinogenic mechanisms. When virtually nothing is known about the mechanisms involved, it seems to us common sense to follow one or two likely leads and see how much can be explained on this basis. We make no apology for adhering to William of Ockham's precept. The analogy with mutagenesis is more pertinent than the Pullmans realize. It is now generally accepted that mutagenesis can occur in one of two ways: by substitution or chemical modification of a nucleotide base (through alkylation, de-amination, etc.), or by intercalation of a molecule of a mutagen such as proflavine between two base pairs, so that during replication the base sequence is changed. Charge-transfer is almost certainly involved in the latter mechanism, which is in fact very similar to our 'sandwich' model.

A new phase of experimental work on chemical carcinogenesis is beginning, and it will soon become apparent whether the Pullmans' hypothesis, or ours, or something quite different, proves more useful in predicting and explaining new observations.

TRANSVERSE SWELLING AND SHRINKAGE OF SOFTWOOD TRACHEIDS

By D. H. PAGE and P. A. TYDEMAN
British Paper and Board Industry Research Association, Kenley, Surrey

THE aqueous swelling and subsequent shrinkage during drying of softwood tracheids in their pulped state is of basic importance to an understanding of the relationship between fibre morphology and properties, and technologically is of interest in the elucidation of the properties of paper made from them.

This subject has been covered adequately by macroscopic techniques, for example, by the estimation of the specific volume of swollen pulps from measurements of hydrodynamic properties[1] and by the measurement of the retention of water by pulps subjected to centrifugation[2]. Little direct microscopic evidence is available, however, and only in the work of Weidner[3] can reference be found to the measurement of dimensional changes of paper-making fibres during drying. The theory put forward by us for the shrinkage, structure and properties of paper[4], based largely on microscopic observation of paper structure and structural changes during drying and tensile straining.

has required confirmation by measurements of tracheid shrinkage and this has led to the work described here.

A few tracheids were collected from aqueous suspension on a wire mesh and microscopic observation was carried out on regions of tracheids lying over the grid openings. Micrographs were taken of the tracheids in their wet state, after drying to equilibrium with 20 per cent relative humidity and again after re-wetting. Due to their natural irregularity along their length, the shrinkage of the tracheids was measured by planimetry of areas of known lengths. A typical series of micrographs is shown in Fig. 1. Only commercial pulps which had been once dried were used, to ensure that dimensional changes caused by the initial collapse of the cell were eliminated. Results obtained from two pulps, a Norway spruce, sulphite pulped, and a Scots pine, sulphate pulped, at various degrees of beating are given in Fig. 2.

It should be borne in mind that the tracheids, being collapsed and ribbon-like in cross-section, tend to position themselves on the grid in such a way that their largest cross-sectional dimension is measured and therefore these results apply only to that dimension.

There are three aspects of interest arising from the results:

(*a*) Although the mean values of shrinkage are in the region of 20–25 per cent of the original tracheid width, individual values ranged from about 5 to 50 per cent, the standard deviation being about 10 per cent. This wide distribution of values does not appear to arise from experimental error and must be accepted as a real indication of the changes in width of tracheids dried under these conditions. This implies that the loss of thermodynamically bound water is not the sole factor in determining tracheid shrinkage and that other mechanisms, such as the loss of capillary water with collapse of the capillaries or the rearrangement of the cellulosic structure under the internal tension, must contribute.

(*b*) The irreversibility of swelling is appreciable, only about 70 per cent of the shrinkage being recovered on re-wetting. This is a finding of importance to the structural theory of paper[4], which states that the irreversibility of shrinkage of paper on re-wetting is attributable largely to the irreversibility of tracheid shrinkage.

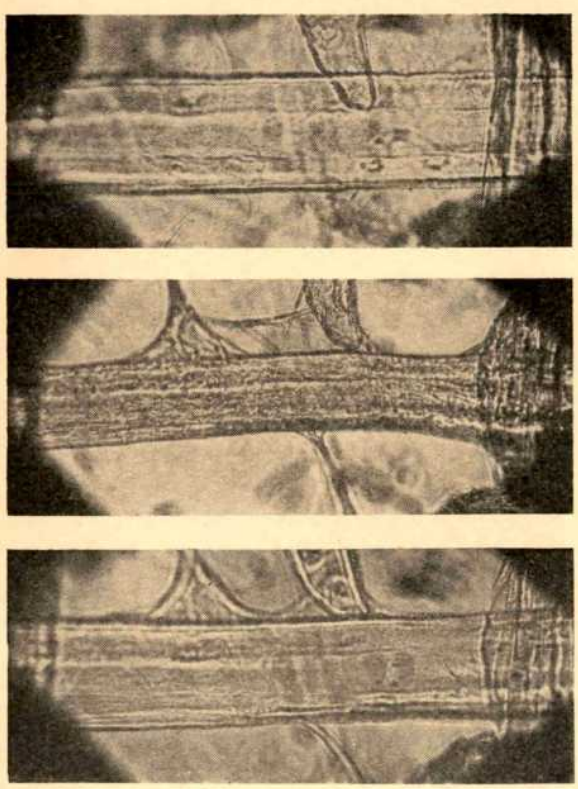

Fig. 1. Scots pine tracheid in the wet, dried and re-wetted state (× 300)

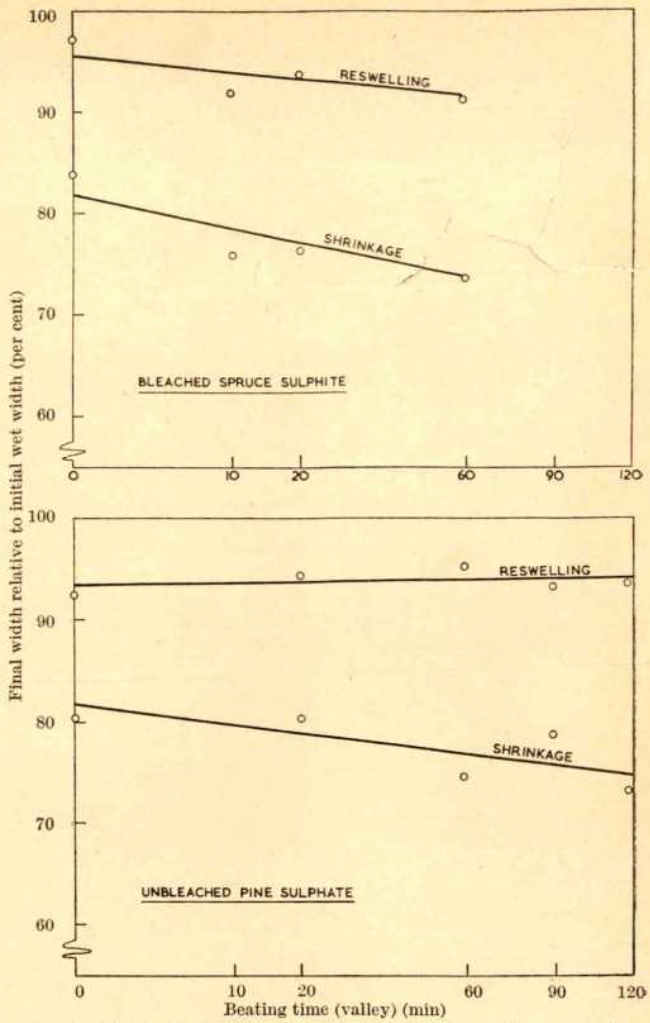

Fig. 2. Effect of beating on the transverse shrinkage and recovery of tracheids. Each point is the mean of measurements on about 15 tracheids

(*c*) The shrinkage is larger for the pulps in the more heavily beaten state. (The results are adequate for both pulps to give statistical confidence to this statement at the 1 per cent level.)

This is a finding of considerable importance technologically and yet is in opposition to the work of Weidner, who found the reverse effect. We believe that the discrepancy can be explained from the difference in experimental conditions between Weidner's work and our own. In his apparatus tracheids were dried on to glass slides. It is now known that the adhesion of fibres to glass during drying precedes shrinkage[4] and will restrict it. Furthermore the areas over which adhesion occurs is considerably larger at higher beating times[5]. These effects would combine to give an apparent decrease in shrinkage for the higher beaten pulp. In our work the use of a wire mesh circumvented this difficulty.

We thank Miss I. Emery for carrying out the measurements and Dr. J. P. Weidner for a private communication in which he agrees with our explanation of the aforementioned discrepancy.

LETTERS TO THE EDITOR

ASTRONOMY

Terrestrial Oceanic Ridges and Lunar Mare Ridges

OCEANIC ridges show striking similarities to lunar wrinkle, or mare, ridges. The following points of comparison may be noted: (*a*) Both the terrestrial and lunar ridges are serpentine and furcate in places. (*b*) The smoothed form of the profiles of oceanic ridges[1] and lunar wrinkle ridges[2] is similar. (*c*) Central rifts characterizing parts of the oceanic system of ridges are also found in several mare ridges. The discovery of rifts capping the lunar ridges was made recently by Kuiper[3] and further announcements have been made by me[4] and by Arthur[5]. (*d*) In those instances where oceanic, and mare, ridges abut on the terrestrial, and lunar, continents, respectively, related lineaments continue the general trend for some distance into the continent in question. (*e*) Some of the terrestrial ridges terminate by wedging out and others end in major strike-slip faults[6]. Precisely these properties describe the terminal stages of lunar wrinkle ridges. For example, the furcating wrinkle ridge in Sinus Aestuum slices the Apennines in strike-slip faults as far as the ruined ring Marco Polo.

Set against these points of similarity, it must be noted that the actual linear dimensions of typically well-developed mare ridges are but one-tenth of those of the oceanic ridges, and the same scaling factor applies to the widths of the rifts in the ridges. (The depths of the lunar rifts have not been measured. These rifts should not be confused with rilles, of known depth, which are also associated with mare ridges.)

The strike-frequency diagram[7] for the segments of lunar wrinkle ridges suggests quite strongly that many of these ridges originated in concealed strike-slip faults. Others, particularly those with a north-to-south trend, probably arose in tension fractures. The anomalously high frequency of occurrence of small craters perched on the crests of the lunar ridges, and their relatively high albedo[8], support the hypothesis that wrinkle ridges are extrusion phenomena. The flows evidently solidified before travelling more than about 10 km across the Moon's surface.

If, as I believe, wrinkle ridges are more recent than the fractures that controlled their gestation, offsets would not be well preserved in the presently observed topography because of the obscuring effects of the extruded lavas. Offsets are still preserved, however, in the lunar continents, where masking and re-moulding through extrusion have been less.

Strike-slip faults that are transverse to the terrestrial oceanic ridges are now well known, yet no longitudinal strike-slip faults have been reported. By analogy with wrinkle ridges, there may be lava flows covering any independent topography on the ocean floors; but longitudinal offsets could be looked for via magnetic anomaly charts. This is, of course, not easy because the anomalies tend to parallel the ridges[9]. On the other hand no one, to my knowledge, has looked for offsets indicating movement along an oceanic rift. Discovery of such movement would bring the analogy between lunar and terrestrial ridges still closer, and would indicate where selenology might supplement geological work.

The analogy may not be complete. Oceanic ridges are now widely explained on the basis of convection currents in the mantle. The currents are rising beneath the ridges, carrying up heat and tearing them apart laterally. Are we to believe that the complex of lunar wrinkle ridges, connecting as they do with the low walls of ghost craters in maria, were all raised by convection currents?

There is no evidence for recent continental drift on the Moon. Indeed, there is a marked uniformity of faulting in set directions[10], and this speaks against very large-scale movements. The Russian photographs of the averted hemisphere of the Moon demonstrate the asymmetric distribution of the lunar maria and continents; and I (ref. 11) have shown that this picture has remained unchanged since Mesozoic time, when the maria were formed. The continental drift theory of the Earth would bring the Afro-Asian countries and the Americas together into one land mass at essentially the same time.

This result may be explained if both the Earth and Moon were heated up by the decay of the long-lived radioactive isotopes. Whereas the lunar continents have not moved appreciably since the Mesozoic, however, the terrestrial continents have moved apart since that time. It would therefore appear that the history of the heating process has been different in the Earth and Moon and, specifically, that the pattern of convection in the two planets has been of a different order—at least in recent times—as Runcorn[12–14] has maintained. It is likely that, in the case of the Earth, complex, high-order patterns of convection have set in, but that such a state of development had not been realized in the Moon.

The wrinkle ridges may possibly be associated with local currents arising during the cooling of the mare lavas; this might help to explain their concentric arrangement in some maria; but, as there is evidence for their association with strike-slip faults, I feel that it would be important to investigate oceanic ridges bearing in mind the possibility of associated longitudinal strike-slip faults rather than purely tensile fractures.

I thank Imperial Chemical Industries, Ltd., for a research fellowship.

Radio-carbon Dates and the Mayan Correlation Problem

IN two papers published in 1956 and 1960[1], Linton Satterthwaite, jun., presented his interpretation of radio-carbon dates obtained from wood from Temples I and IV and Structure 10 at Tikal, Guatemala. He concluded that the Goodman–Thompson correlation of the Mayan and Christian calendars, or a variant thereof, should be accepted. In this communication, I propose to point out certain weaknesses in his basic assumptions, and to offer alternatives which, in my opinion, are as likely to be valid as his.

To simplify matters for the reader, I shall elect to refer only to the 1960 paper. In this, with Dr. Elizabeth Ralph, Satterthwaite presented radio-carbon dates obtained at the

University of Pennsylvania for samples of wood taken from ten beams in Temple IV and six beams of Temple I, and offered for comparison radio-carbon dates obtained at other institutions. For the ten beams in Temple IV dated at the University of Pennsylvania, an average date of A.D. 743 ± 48 y. is offered. This may be compared with a date of A.D. 751 May for 9–16–0–0–0 according to the Goodman–Thompson correlation. All dates given in this note are in the Julian Calendar.

Satterthwaite quotes four dates obtained at other institutions for Temple IV and Structure 10, the latter assumed to be within ten years of the former, an assumption I am willing to accept. They are, with one Pennsylvania date added, as follows:

			A.D.	
1951	Kulp *et al.*	Columbia University	481 ± 120	weight 3
1954	Libby	University of Chicago	433 ± 170	,, 2
1954	Libby	University of Chicago	469 ± 60	,, 6
1958	Broeckway *et al.*	Columbia University	456 ± 60	,, 6
1960	Ralph	University of Pennsylvania	465 ± 85	,, 4

The final date listed is one associated with the University of Pennsylvania sample number 229, which Satterthwaite elected to discard, saying the beam from which it came must be "an older re-used beam". He did not offer any evidence in favour of this assumption, no carving left over from a previous use, only the fact that it appeared to be older.

The weights I have assigned above to the five dates are approximately inversely proportional to the standard deviations of the dates. With them, one finds a weighted average of the five dates, A.D. 463 ± 10 y. Here, the standard deviation is a measure only of the scatter of the five values used. The average date obtained may be compared with dates as follows: 473 A.D., March 19 for 9–16–0–0–0 according to the Smiley correlation[2], 490, November 4 for the Makemson correlation[3] and 491, July 8 for the Spinden correlation[4].

I now suggest that the earlier date, A.D. 463, is the one which should be assigned to Temple IV and Structure 10 at Tikal, and that the University of Pennsylvania date, A.D. 743, represents beams which were installed at a later date approximately 280 years (perhaps 260 years, or five calendar rounds) after the original construction. Satterthwaite himself directs attention (p. 177) to damage to beams due to termites. If the University of Pennsylvania samples were carefully chosen from the best-preserved beams in the temples, they might easily have been taken from beams which had replaced earlier ones in the original structure. If the Mayans considered zapote (sapodilla) wood to be termite-resistant, it would explain why at least one old zapote beam remained in the structure, and other beams, perhaps of other wood less resistant to termites, had been replaced by zapote beams.

There is, of course, a weakness in the radio-carbon approach to the problem in that the presence of a date on a beam does not assure one that the wood belongs to that epoch. The beam might be a part of a re-used beam, or it might be of wood that was cut early and allowed to season before use, or it might represent timber that was later cut and carved to replace a beam damaged by termites, fire, storms, or other ravages of time. There is also the question as to whether the dates, when carved on beams, represented predictions for the future, or records of observations made in the past. I am inclined to accept the latter point of view, but this matter is not important here.

It now appears that the matter of the correlation of the Mayan and Christian calendars will be settled by astronomical means, perhaps with help from dendrochronology.

METEOROLOGY

Atmospheric Hydrogen Sulphide Concentrations during the London Fog of December 1962

Very few figures have been published concerning the hydrogen sulphide content of the atmosphere. Information on this subject was required in connexion with investigations on the tarnishing of silver, and determinations have been made at the Post Office Research Station, London, N.W.2, at about weekly intervals for the past 2·5 years. The method used was to suck, by means of a small electric pump, a measured volume of pre-filtered air through filter paper impregnated with silver nitrate and to compare the resultant silver sulphide stain with standards. The site is on a hill 240 ft. above sea-level in north-west suburban London. Immediate surroundings are residential and open space with typical suburban mixed residential, light industrial, railway and power station development beyond.

The range of results may be broadly summarized as follows:

Season and weather	Approximate hydrogen sulphide content of atmosphere Parts per thousand million by volume (p.p.t.m.)
Summer, very clear, fresh conditions with wind from a westerly quarter	0·1 or less
Summer, average conditions	0·1–0·5
Winter, average conditions	0·5–1
Winter, fog; drift of air from the East	1–5

These figures are only intended to give some indication of the values generally to be expected under given conditions since many factors, including, in particular, wind direction and velocity, exert a great influence. An easterly wind brings polluted air from London to the site, whereas wind from a westerly quarter has passed over regions much less built up and industrialized and the latter is therefore associated with lower hydrogen sulphide contents.

During the foggy weather early in December 1962 measurements of atmospheric hydrogen sulphide were made with an automatic apparatus that had just become available.

Table 1

The principle used was the same as in the method for intermittent determinations previously mentioned, the stains being formed on a strip of impregnated paper which was automatically advanced at the end of each test period. Tests, each lasting 32 min, followed each other without intervals on December 6, 1962, a day of continuous thick fog, several preceding days also having been calm and foggy. 32-min tests were continued on December 7 when the fog was clearing; but on December 10, after a week-end of strong westerly winds, when a moderate north-west breeze was still blowing, it became necessary to extend the test periods to 3 h to obtain stains of measurable intensity.

Although it remained apparently calm near ground-level on December 6, the rise in atmospheric hydrogen sulphide between 15·28 and 18·08 may have been caused by a slight air drift from the south-east bringing more heavily polluted air from the central London area, this being indicated by the extension of the area of dense fog in a north-westerly direction from this Station during the period concerned. Some air movement occurred during the night of December 6–7, altering the direction of the wind-vane on top of the building from east to south, reducing the fog density, and lowering the hydrogen sulphide content of the atmosphere. The time of the change in direction is unknown, but it might well have been associated with the marked fall in hydrogen sulphide that occurred at 18.40 on December 6. The wind-vane was invisible at this time.

The morning of December 7 remained calm and after an initial fall in hydrogen sulphide corresponding to the clearing of the fog the content was substantially constant until the afternoon when a light south-west breeze caused progressive reduction. The strong westerly winds of the week-end December 8–9, continuing as a moderate north-west breeze on December 10, resulted in lower atmospheric hydrogen sulphide contents than usual for the time of the year.

The figures for the period 16.00 onwards on December 6 are the highest ever recorded in our tests. Previously, the maximum observed at this Station was 5 p.p.t.m., although in certain other areas subject to heavy, specific, industrial pollution, values up to 10 p.p.t.m. have occasionally been found under normal weather conditions.

I thank the Engineer-in-Chief of the Post Office for permission to use the information contained in this communication.

Ice Nucleation by Metaldehyde

During recent years ice-nucleation by some organic substances has been investigated with increasing interest in fundamental, as well as in practical, fields. Some steroids can nucleate ice crystals at temperatures as high as − 1° C when prepared by thermal recrystallization[1,2]. One of the amino-acids[3] is reported to nucleate ice at −4·5° C. Although many of them have complicated molecular and crystal structures and are not common, they may be useful in understanding heterogeneous ice-nucleation. For application to cloud-seeding, phloroglucinol[4], α-phenazine[5] and a few others have been found among the common organic compounds to overcome the faults of silver iodide as a practical seeding material, such as photolytic inactivation and high price. The wide variety of organic compounds gives some hope of finding improved cloud-seeding materials.

Metaldehyde $(CH_3CHO)_4$, a cyclic tetramer of acetaldehyde, was recently found to have remarkable properties in ice-nucleation, producing ice-crystals at temperatures as high as −0·4° C under suitable conditions.

Ice-nucleating ability depended on the method of preparation, dispersal and particle size.

Prepared by recrystallization from ethanolic solution by cooling, the crystals were ground and dispersed into the air. After sedimentation, those smaller than 13μ in diameter were collected on an inactivated metal tray and cooled on the top of an aluminium plate in a cold chamber. The temperature of the plate was measured by a copper-constantan thermocouple. Water vapour was supplied for 10 min and the crystals which had formed were detected by the addition of a supercooled aqueous solution of polyvinyl alcohol (1 or 5 per cent, depending on the temperature), after which they grew to visible size. 1 g of crystals treated in this way produced 10^4 ice crystals at −0·6° C. At −2° C a large proportion of the crushed crystals (10^6/g) was observed to nucleate ice. For comparison, the onset of ice-formation of ground silver iodide using the same method was −4° C, and of ground α-phenazine −3·5° C.

10^4 ice-crystals were generated at −0·4° C from 1 g of sublimed metaldehyde crystals. At −10° C the sublimed metaldehyde crystals gave as many nuclei per gram as silver iodide, when detected in a cold chamber with a supercooled 5 per cent solution of polyvinyl alcohol at the bottom, but the ice-crystals were produced more slowly. The soap film technique[6] yielded slightly different temperatures for the onset of nucleation by crushed crystals between − 1° and −2° C. For nucleation at warm temperature, metaldehyde therefore seems to be preferable to silver iodide.

It is known that silver iodide smoke released in the atmosphere decays due to the action of sunlight. This is important in cloud-seeding applications, so that the solar effect on metaldehyde was tested. Ground particles on the metal tray were placed in sunlight on a fine day in April, in Sydney, for 2 h and tested at −2° C, and no significant change of ability to nucleate was observed. However, when they were placed under the sunlight for more than 1 h at a temperature higher than 55° C, the nucleating property disappeared completely. Metaldehyde sublimes at 112° C but decomposes partially at more than 80° C giving paraldehyde, a cyclic trimer of acetaldehyde. Therefore the observed inactivation could be either evaporation or decomposition. As long as the nuclei were kept under 33° C for less than 2 h the activity at −2° C remained unchanged. It therefore seems that the use of metaldehyde in cloud-seeding operations should be seriously considered, for it is both more efficient and more economical at the temperatures where natural ice nuclei are very rare.

A possible reason for its nucleating ability is suggested by its molecular and crystal structure, determined by Pauling and Carpenter[7]. The tetragonal crystal of metaldehyde recrystallized from absolute alcohol has a body-centred unit of structure with $a_0 = 10{\cdot}40$ Å and $c_0 = 4{\cdot}11$ Å containing two molecules of the tetramer

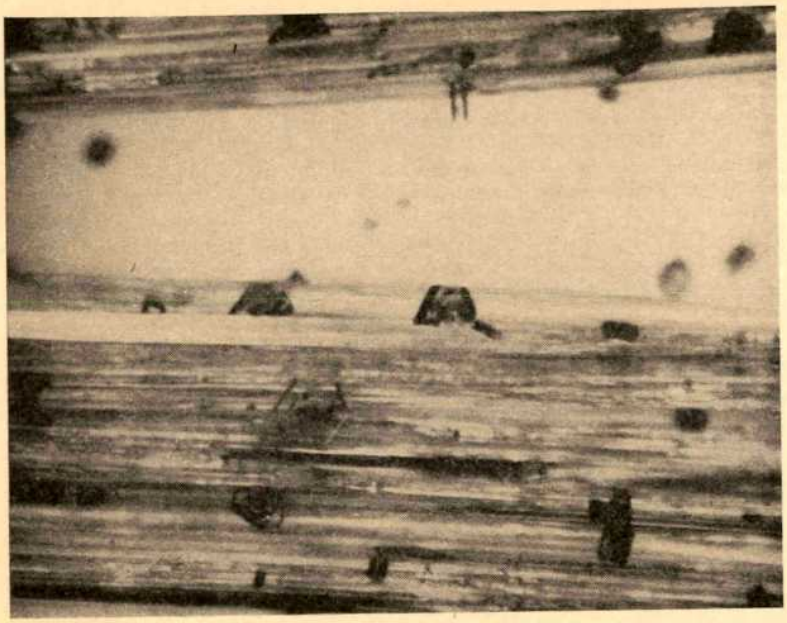

Fig. 1. Ice crystals growing on the prism plane of metaldehyde at −15° C

$(CH_3CHO)_4$. It has a pronounced prismatic cleavage due to its dipolar molecular structure and the resulting planes are parallel to its c-axis. For a tetragonal unit $(\sqrt{2}\,a_0)^2 \times 2c_0$, taken from the metaldehyde lattice, three possible orientations of ice were estimated to match in three directions of the unit, [1$\bar{1}$0], [110] and c-axis with reasonable misfits (Table 1). Observation with a microscope of ice nucleation on metaldehyde crystals obtained from ethanolic solution showed that these three orientations appeared very often; however, some others were also seen. Fig. 1 shows some epitaxial growth of ice on long needles of metaldehyde crystals at −15° C. A smooth prism plane gave few nucleation sites and ice crystals were more likely to be observed at the large steps and crushed parts. Although ice-formation by sublimation was easily seen at these temperatures, freezing of condensed water was predominant at higher temperatures.

I thank Dr. E. K. Bigg for suggestions on ice-crystal detection and the Commonwealth Scientific and Industrial Research Organization for a fellowship which enabled this work to be carried out while on leave from the Chemistry Department, Nagoya University, Japan.

PHYSICS

Units in Vacuum Measurements

Along with the growing unification of the various branches of physics there has been a trend toward unifying our systems of units. Originally the various branches developed systems of units peculiar to each; but as the branches have overlapped and merged some special units have been discarded in favour of those related in a simple way to the units selected as fundamental. The joule, for example, is beginning to replace the calorie as a heat unit, and meteorologists are changing from the inch of mercury to the bar for barometric pressures.

In the light of this general trend, one may ask why we continue in vacuum work to use the millimetre of mercury, and the closely related torr, which are not simply related to the fundamental units, but are specific to the field of pressure measurements. Why do we not use the dyne/cm², for example? There is a historical reason, of course. Early measurements of pressure were made with the mercury manometer, which is a reliable absolute instrument, or with instruments calibrated against it. For pressures too low for the simple manometer we have the McLeod gauge, which is still an absolute instrument. Although we now have ionization gauges to measure pressures which the McLeod gauge cannot measure, these gauges are not absolute, and we calibrate them against the McLeod gauge. It is quite natural, then, to express their calibrations in the same units as we use for the standard gauges. The typical user of one of these ionization gauges may not be impressed by this argument, however, since he may never have occasion to calibrate his gauge against a manometer, in which case the millimetre of mercury loses its special claim.

These arguments are something of a digression from the main question, however. There is a more fundamental point to raise about vacuum units. Let us consider what vacuum gauges actually measure. A mercury manometer measures pressure directly. However, an ionization gauge counts a sample of ionized molecules, so in the operational sense it measures molecular density. Although in most circumstances prevailing in vacuum work molecular density and pressure are simply proportional, we can show from the ideal gas law that the general relation is $n \sim P/T$. This has been discussed in more detail elsewhere[1]. It is sufficient here to point out that an ionization gauge does not measure pressure directly. It should also be pointed out that whereas molecular density has a clear and unequivocal meaning at any pressure, the term 'pressure' begins to lose its conventional meaning somewhere in the very high vacuum region.

Perhaps we are in our present state of confusion on these matters because ionization gauges are calibrated against pressure gauges. If we could construct an ionization gauge of absolutely known sampling efficiency it would be an absolute gauge. It might then be clearer that the gauge counts molecules, rather than measuring pressure. There would then be little argument against calibrating it to read in molecules/cm³, or some such unit. From the fact that at a pressure of 760 torr there are $6{\cdot}02 \times 10^{23}$ molecules/mole, it is a straightforward calculation to show that 1·00 molecule/cm³ corresponds to a 'pressure' of $2{\cdot}83 \times 10^{-17}$ torr, or, in the mks system, 1·00 molecule/m³ corresponds to $2{\cdot}83 \times 10^{-23}$ torr.

Because of the wide range of densities encountered in vacuum work these days, a further change is worth considering. In vacuum work one really thinks more in logarithmic than in linear terms. A constant-speed pump reduces the pressure in an ideal chamber at a rate proportional to e^{-at}, which plots as a straight line on a log pressure versus time plot. There are now available on the market electrometers and gauge controls with logarithmic scales covering as many as six decades. Would it not be reasonable to have a logarithmic density unit, much like the chemists' pH scale? If the new unit were to be defined as the logarithm of the number of molecules per m³, the zero would be at 1·00 molecule/m³, or $2{\cdot}83 \times 10^{-23}$ torr. A pressure of $1{\cdot}00 \times 10^{-6}$ torr would correspond to a

density of 16·55 logarithmic units. With the suggested choice of a zero point, it is not likely that we would be using negative logarithms very much. Indicators with a logarithmic response could use a simple linear scale on the indicating meter, and linear paper could be used on recorders. The indicator could be made to take care of varying gauge constants by incorporating a zero-suppression circuit.

With these advantages, there is one disadvantage of a logarithmic unit that must be admitted. In residual gas analysis it would not be convenient to calculate total densities from partial densities in logarithmic units. Whether or not this would be a serious drawback depends on how important such calculations are relative to the entire vacuum field. It might be desirable to have both a logarithmic and a linear unit of density. Whichever the choice, of either or both, it seems that the basic vacuum unit in high-vacuum work should be one of molecular density, rather than pressure.

Inhomogeneous Problems in Elasticity or Heat Conduction

N. LOUAT[1] has recently described a method of solving two-dimensional problems in elasticity by the replacement of free surfaces by two mutually independent arrays of edge dislocations chosen so as to produce zero stress at each free surface. M. A. Jaswon[2] has described a similar procedure in which prescribed boundary displacements may be achieved by means of boundary distributions of point forces chosen to satisfy a set of Fredholm integral equations. The attraction of each method lies in the fact that the effect of a point force within an infinite medium may be calculated from a simple formula. Furthermore, the use of digital computer techniques allows the superposition of a large number of such forces.

It may be worth while to note that the technique of summation of the effect of point forces is also a useful one for treatment of inhomogeneous problems in elasticity or heat conduction. Such problems, although of considerable practical importance, have received little attention in the literature.

Suppose that a solution of the equations of elasticity has been obtained for homogeneous elastic material subject to given boundary conditions, boundary forces, and body forces. Let v_1, v_2, v_3 denote the components of the displacement at a general point, let e_{ij} denote $\frac{1}{2}(\partial v_i/\partial x_j + \partial v_j/\partial x_i)$, and let θ denote $e_{11}+e_{22}+e_{33}$. It may be shown that if the elastic parameters λ and μ suffer a small change from constant values of λ_0 and μ_0 to become: $\lambda = \lambda_0 + l(x_1,x_2,x_3)$, $\mu = \mu_0 + m(x_1,x_2,x_3)$, then each displacement v_1,v_2,v_3 is increased by an amount w_1,w_2,w_3 which may be found as the result of applying to the homogeneous material an internal force distribution of components[3]:

$$g_i = 2\sum_j \partial(me_{ij})/\partial x_j + \partial(l\theta)/\partial x_i \qquad (1)$$

The resulting stress distribution may readily be found in terms of the total displacement $v_i + w_i$.

The form of equation (1) is interesting in that it may be expressed as a sum of some terms such as $e_{ij}\partial m/\partial x_j$ which become large when m changes abruptly, and some terms such as $m\partial e_{ij}/\partial x_j$ which become large whenever m differs from zero in a region of high stress. Thus, if an elastic material contains intrusions of material of different elastic constants the effect of the intrusions is equivalent to a set of forces distributed over their surfaces and another set distributed throughout their volume. In many instances this second set of forces is small so that the intrusions may be replaced by forces on their surfaces.

The analysis outlined above is not restricted to two-dimensional problems.

A similar treatment may be given of the equation of heat conduction through inhomogeneous material. The equation of heat conduction in a solid is:

$$\nabla k.\nabla T + k\nabla^2 T = g\partial T/\partial t \qquad (2)$$

where T is the temperature, k is the conductivity, and $g = \rho c$, where ρ is the density and c is the specific heat. Suppose that for constant parameters k_0 and g_0 a solution is $T_0(x,y,z,t)$. If the parameters k and g change to become: $k = k_0 + Ak_1(x,y,z)$, $g = g_0 + Ag_1(x,y,z)$, then equation (2) may be satisfied by a solution $T(x,y,z,t)$ of the form:

$$T(x,y,z,t) = \sum_{n=0}^{\infty} A^n T_n(x,y,z,t)$$

where the T_n are found in succession as solutions of the equations:

$$k_0\nabla^2 T_n - g_0\partial T_n/\partial t = g_1\partial T_{n-1}/\partial t - \nabla(k_1\nabla T_{n-1}) \qquad (3)$$

The constant A is chosen to specify the scale of the inhomogeneities and has no other physical significance.

Each of equations (3) represents a temperature distribution T_n in a homogeneous material that contains a distribution of heat sources or sinks corresponding to the terms on the right-hand side. Thus, the temperature distribution within inhomogeneous material may be investigated in terms of that within homogeneous material containing a suitable distribution of heat sources.

An advantage of the form of equations (1) and (3) is that it is not necessary to choose a co-ordinate system to fit the shape of the inhomogeneities; thus the technique may be applied to treat the effect of irregularities of general shape. Some preliminary investigation has shown that there are many instances where use of equations (3) leads to a solution the terms of which may be found by algebraic recurrence relations. The technique is now being applied to several problems of practical interest.

Use of Long Cavities for Aqueous Samples in an Electron Spin Resonance Spectrometer

IN a comment on the electron spin resonance spectrometer designed especially for aqueous samples which has been described recently by Cook and Mallard[1], Stoodley[2] has calculated that the method of using a multimode microwave cavity tends to degrade the sensitivity rather than improve it. I would like to point out that support for Stoodley's result is provided by a spectrum recorded by Varian Associates on their aqueous sample spectrometer and published in some recent advertising material[3]. The signal-to-noise for this spectrum is some thirty times better than for that presented by Cook and Mallard. Further, although the sensitivity was said to be comparable with that obtained by Commoner *et al.*[4], in fact these workers claim a figure of 2·5 to 5×10^{-7} molar of Mn^{++} while that of Cook and Mallard is 3×10^{-6} molar. The sensitivity of the Varian spectrometer expressed in these terms is 1×10^{-7} molar. The difference in sensitivity between that achieved by Cook and Mallard and by Varian can be attributed to three causes. First, sensitivity is proportional to the square root of the microwave power and, while Varian quote 180 mW, Cook and Mallard appear to be using a 723 *A/B* klystron which gives 20 mW. Hence the sensitivity drops by a factor of three. Secondly,

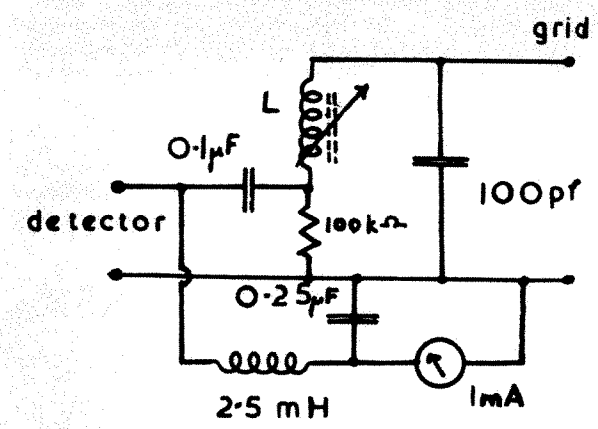

Fig. 1. Improved input circuit for cascode or pentode pre-amplifier giving a near-ideal noise figure (L_1 = 1 mH, one section of 'Radiospares' 465 kc/s tuned transformer)

according to Stoodley, the cavity design should give a sensitivity which is 4·4 times worse than optimum. The remaining factor of 2·2 is due to deficiencies in the pre-amplifier used by Cook and Mallard.

The pre-amplifier, which uses the cascode circuit, can be criticized in two respects. First, when a cascode is used as a radiofrequency amplifier it should be operated with an anode load resistance of the same order as the anode slope resistance of the valve[5] (10 $K\Omega$). To use a higher value results in an increase in gain from approximately μ to μ^2, where μ is the amplification factor of the valve, but also causes the gain of the first stage to rise from unity to μ, thus causing instability and failure to realize the original idea behind the cascode circuit. The design published by Ingram[6] is also subject to this criticism. In both cases a resistance of the order of 10 $K\Omega$ should be shunted across the output tuned circuit which otherwise would typically have an effective resistance of the order of 300 $K\Omega$. The other, equally serious, criticism is that Cook and Mallard have not matched the input of the amplifier to the crystal. A complete treatment of this point is given by Moxon[7], and a practical input circuit following Moxon's analysis is shown in Fig. 1. Assuming an equivalent noise resistance of 600 Ω for the 12AT7 and a crystal impedance of 400 Ω and neglecting regeneration, the calculated noise figure for Cook and Mallard's circuit should be 4 db. With matching applied and assuming a Q factor of 100 and a capacity of 100 pF, this figure is reduced to 0·35 db for the cascode, and 0·5 db for an EF89 pentode with an equivalent noise resistance of 1 $K\Omega$. Thus on theoretical grounds there is no objection to the cascode circuit provided that the output is suitably damped and an input matching circuit is used. It should be noted, however, that a conventional pentode circuit gives a noise figure which is also nearly ideal and no significant advantage is obtained by using the cascode at such low frequencies (465 kc/s).

In support of these calculations the appropriate circuits have been constructed and noise figures measured for a source impedance of 400 Ω. The results are quoted below.

Cook and Mallard's circuit as published	7 db
Cook and Mallard's circuit with input match	1 db
EF89 pentode with input match	1 db

The first of these results is worse than that calculated and may be explained as being due to regeneration. The others agree within experimental error.

One remaining comment is that in Cook and Mallard's circuit there is a 10 $K\Omega$ resistor in series with the d.c. path of the crystal. It is generally recognized that this deteriorates the sensitivity of a crystal detector and the resistor should therefore be replaced by a choke. Cook and Mallard's remark that choke decoupling caused oscillation confirms the view that the circuit as presented is inherently unstable. A choke could have been used satisfactorily if the output had been suitably loaded.

It may therefore be concluded that the sensitivity of the spectrometer described by Cook and Mallard can be improved by reverting to the conventional cavity design described by Stoodley and used by Varian and also by adopting the input circuit indicated in the figure for the pre-amplifier. Further, no deterioration in sensitivity will result if the cascode circuit is discarded in favour of a conventional pentode.

GEOLOGY

High-temperature Minerals in Non-metamorphosed Sediments in Israel

An unusual mineral assemblage was recently found in a sedimentary rock sequence of Maastrichtian to Palæocene age, the so-called 'Mottled Zone', in Israel and adjoining parts of Jordan[1]. This formation is known to occur in at least four widely separated places: the Hatrurim basin west of the Dead Sea, the Beersheba valley in the northern Negev, the Ramlah area in the coastal plain, and at Ma'aleh Adumim in the Jordanian part of the Judean desert.

The most characteristic rock of this formation is largely composed of calcite and spurrite, the latter locally dominant, and minor amounts of pyrite, apatite, spinel, a dicalcium silicate, gehlenite, and a mineral identical with, or closely related to, brownmillerite. (We thank Mr. E. Sass, of the Hebrew University, Jerusalem, who helped in the determination of this mineral.) This rock is cut by numerous small veinlets filled by rare minerals, including bayerite, vaterite, portlandite, hydrated calcium silicates of the tobermorite group, and thaumasite. Ettringite is sufficiently abundant to be considered rock forming. These minerals are associated with calcite, aragonite, gypsum, hæmatite, and many others at present under investigation.

Anhydrous calcium silicates, such as spurrite, are so far known only from limestones, contact-metamorphosed by igneous intrusions. The accompanying hydrous calcium silicates are generally explained by the action of hydrothermal solutions on the high-temperature silicates. Mineral assemblages of this kind occur in the classic localities of Crestmore, California[2] (gehlenite, ettringite, thaumasite, tobermorites); Scawt Hill, Northern Ireland[3,4] (gehlenite, spurrite, larnite, ettringite, portlandite); and Ballycragy, Northern Ireland[5,6] (vaterite, larnite, tobermorites, thaumasite). Ettringite was recently also found in the high-temperature zinc deposit of Franklin, New Jersey[7]; its type locality is Ettringen, Germany[8], where it occurs together with portlandite. Thaumasite is known also in magmatic sulphides (Sweden, Norway, Utah) and in basic lavas (New Jersey, Hungary, Northern Ireland)[9]. Portlandite has been reported from calcareous xenoliths on Mount Vesuvius[10]. Brownmillerite has hitherto not been found in nature, but is an essential constituent of Portland cement clinker. Thus, the mineral assemblage discussed here occurs either in magmatic rocks or in highly metamorphosed sediments of the sanidinite facies; but more than any other natural occurrence it resembles Portland cement and its alteration products.

The unique feature of the 'Mottled Zone' mineralization is the occurrence of high-temperature minerals and of secondary minerals derived from them in a sedimentary sequence unaffected by either contact or regional metamorphism. Contact metamorphism is excluded by field evidence, as well as by the constant stratigraphic position of these deposits at various places; the tectonic position of the formation in areas where folding is absent or very slight excludes regional metamorphism. Moreover, the calcite–spurrite formation in one of the localities here described, though heavily eroded, extends over an area of 5 × 8 km and reaches a thickness of up to 80 m, in contrast with the occurrence so far known where rocks carrying these minerals are generally confined to narrow contact zones.

The mechanism by which these minerals developed in the sedimentary environment of the 'Mottled Zone' is now being examined. It is tentatively suggested that the energy required for the formation of the high-temperature silicates was in this case supplied not externally from magmatic sources, but internally by subsurface oxidation of organic matter and sulphides, both of which were abundant in the original rock. This process might be compared to the spontaneous combustion of artificial slag heaps, also known as coal tips.

Ngurumanite, a New Hypabyssal Alkaline Rock from Kenya

In June 1959, E. P. Saggerson and B. H. Baker of the Geological Survey of Kenya discovered a number of small alkaline intrusions in upper Tertiary lavas on the Nguruman Escarpment, which forms the western wall of the Rift Valley about seventy miles south west of Nairobi. During a detailed examination of these intrusions in 1960, we found the alkaline rocks to be emplaced in a flow of ankaratrite (biotite-olivine melanephelinite), that is evidently intercalated in more common olivine basalts. The intrusions, which are probably of upper Tertiary age, are closely controlled by two north–south vertical fault zones in the ankaratrite. Narrow dykes feed sills about 2 ft. thick and these thin rapidly into an intricate network of veins.

The medium- to coarse-grained intrusive rocks consist largely of pyroxene and altered nepheline and are thus somewhat similar to many melteigites: they differ radically, however, in containing an iron-rich mesostasis and numerous vug-like segregations of zeolites and calcite. The combination of these unusual features has led us to propose a new rock name, 'ngurumanite', given after the Nguruman Escarpment where the rock was discovered.

Although most of the ngurumanite is distinctly red-brown, thin green veins of similar composition also occur, field relationships showing that the greenish intrusions were emplaced after red varieties. The close spatial relationship and the similarity in mineral and chemical composition of the ngurumanites and host ankaratrite strongly suggest that all the rocks were derived from a common magma and that ngurumanite can be considered a hypabyssal equivalent of the ankaratrite. Lacroix has described other hypabyssal equivalents of ankaratrites, though the Kenya rocks lack the felspar, biotite, hornblende and olivine of tamaraïte[1] and felspar, biotite and olivine of fasinite[2].

A full description of the rocks and their petrogenetic significance will appear elsewhere. Meanwhile, we thank the Commissioner of Mines and Geology, Kenya, for permission to publish this article.

GEOCHEMISTRY

Comparative Uranium and Thorium Analyses of Basic and Ultra-basic Rocks

Recently a number of new analyses using neutron activation and isotope dilution techniques have been reported for uranium and thorium in certain basic rocks (that is, eclogites) and ultra-basic rocks (that is, peridotites and dunites) which are variously considered to represent materials forming the Earth's upper mantle[1,2]. In view of the significance of these results with respect to the radioactive generation of heat in the upper mantle, it is of some importance to establish the interrelation of the results reported by the various workers interested in the problem of the determination of low-level uranium and thorium abundances in rocks.

Tilton *et al.* have variously reported uranium abundances (using both isotope dilution and neutron activation techniques) and thorium abundances (using only isotope dilution techniques) in both basic and ultra-basic rocks[3–4]. Through the courtesy of Dr. Tilton and Dr. Reed aliquots of the samples of four of the rocks analysed by them were made available to us for the simultaneous determination of uranium and thorium by a neutron activation technique described elsewhere[5]. Of the four rocks analysed here, two are of basic composition (the Hualalai basalt and the eclogite from Salt Lake Crater) and two are of ultra-basic composition (the Twin Sisters dunite and the Gila dunite nodule).

Basalt, Hualalai, Hawaii. Probably as a result of the relatively high levels of uranium and thorium existing in this rock, together with the high state of homogeneity of the sample, there is extremely good agreement between values reported previously and our results.

Pyroxene-rich Eclogite, Salt Lake Crater, Hawaii. Tilton and Reed[2] have reported that the rock used for this sample was contaminated with carbonate. However, they removed this carbonate by leaching the rock powder in hot 4 N hydrochloric acid for 30 min and determined uranium in the leachings as well as uranium and thorium in the leached rock. The rock samples analysed in the work recorded here were similarly leached with hot 4 N hydrochloric acid, and 4·8 and 4·0 per cent respectively of each sample were found to be soluble. The thorium content of the leachings was determined but the uranium analyses were unfortunately lost. The uranium content of the leached rock was found to be identical with that reported by Tilton and Reed, but our thorium figure is some 26 per cent higher than their value. We have previously analysed an olivine eclogite nodule (*R*419) also from the Salt Lake Crater and found 0·042 p.p.m. uranium and 0·10 p.p.m. thorium[1]. At that time it was pointed out that the thorium/uranium ratio for this oceanic eclogite was 2·4 and lower than the range for eclogites

Table 1. Comparative Uranium and Thorium Analyses of Basic and Ultra-basic Rocks

[a] Tilton and Reed (ref. 2). [b] Hamaguchi, Reed and Turkevich (ref. 3). [c] Goles (personal communication). [d] Tilton (ref. 4). [e] Precisions calculated from counting statistics.

from deep-seated pipes in the continental regions (3·5–5·8)[1]. The ratio for the carbonate-contaminated rock (using Tilton and Reed's analyses) is also 2·4 but the ratio for the leached rock (on our analyses) is 4·2, which is identical to the average ratio calculated previously for the continental pipe eclogites. It may well be that some carbonate contamination in our previous sample *R*419 reduced the thorium/uranium ratio to the low value observed, since (on the basis of Tilton and Reed's uranium and our thorium analyses) the thorium/uranium ratio of the leachings is only 0·37.

Dunite, Gila, Arizona. The previously reported analyses for uranium are unusual in that the activation results are 2–3 times larger than the isotope dilution results. Our uranium determinations show a relatively small variability (suggesting sample homogeneity) and are consistent with the lower isotope dilution results. Our thorium results also show little variation.

The rock is a dunite nodule associated with basaltic rocks in Arizona and is of interest because it has been suggested that these nodules are derived from upper mantle material[6]. The thorium/uranium ratios for the samples are 2·8 and 2·9 and are close to the range for upper mantle materials discussed elsewhere[1].

Dunite, Twin Sisters, Washington, United States. The previously reported uranium results show more than an order of magnitude variation between isotope dilution and activation methods and more than a factor of three variation between different samples analysed by the same activation method (Table 1). Dr. G. Goles has kindly supplied us with a previously unpublished uranium analysis for the same rock sample using another activation technique, and his result agrees quite well with the highest activation values reported by Tilton and Reed. The two uranium determinations from this investigation show an unprecedented variability with the lower value close to the highest activation results reported previously while the other value is some six times larger. It is significant that the thorium values for each sample (which are both very much less than a previous isotope dilution result) show a corresponding variability so that the thorium/uranium ratios on each sample are 0·8 and 0·7, respectively. This would seem to constitute good evidence that the variability is real and is a result of inhomogeneities in the original sample. In view of the variations observed, it is difficult to assign meaningful uranium and thorium abundances to this rock; but it does seem as if the isotope dilution results reported previously are too high.

The Twin Sisters dunite is generally regarded as an alpine-type peridotite which may represent upper mantle material which has been intruded into the crust during an orogenic episode[7]. However, the very low thorium/uranium ratio in the rock is far outside the range calculated on other evidence for possible upper mantle material. This does not rule out an upper mantle origin for this peridotite but it would seem to indicate that if it is so derived then it must have had its original thorium/uranium ratio modified during or subsequent to its intrusion into the crust.

This work was carried out under a research grant from the Australian Institute of Nuclear Science and Engineering, using facilities generously made available by the Australian Atomic Energy Commission.

CHEMISTRY

Evidence for New Phase occurring in Portland Cements

The X-ray powder diffraction patterns normally obtained from Portland cements contain only lines which can with confidence be said to be due to the presence of the four major phases, alite (modified C_3S), C_2S, C_3A^*, a ferrite phase in the solid solution series C_6A_2F–C_4AF–C_2F and minor constituents such as CaO, MgO and $CaSO_4$. Recently, however, I have obtained from a few cements diffraction patterns in which a number of unusual lines were present. The new lines, from their position and intensity, appear to be produced by material having a structure closely similar to perovskite, that is, orthorhombic, pseudo-cubic, $a' = 3{\cdot}8$ Å. This material cannot be true perovskite ($CaO.TiO_2$) because the TiO_2 content of the cements is too small (Table 1). The structure of C_3A bears some resemblance to that of perovskite, being cubic with a cell-side four times that of the pseudo-cell of perovskite, and careful consideration of the intensities of reflexions suggests that these cements may contain little or no C_3A and that it has been replaced by a similar phase with the lower symmetry of perovskite.

One possibility is that the new phase is NC_8A_3, described by Brownmiller and Bogue[1], or KC_8A_3, described by Suzukawa[2], or more likely, since the two compounds are isomorphous, a solid solution $\binom{N}{K}C_8A_3$; but for the available alumina to be combined as this compound rather than C_3A, nearly all the alkali in the cements would be required. The usual view[3] is that the alkali in the cements is preferentially combined as Na_2SO_4 and K_2SO_4

and the remainder as $KC_{23}S_{12}$ and NC_8A_3, and it is perhaps significant that in the three clinkers, A, B and C, the SO_3 content is low and the alkali may thus have been free to form $\binom{N}{K}C_8A_3$.

Unfortunately, chemical analyses of residues which have been enriched in the new phase by selective hydrolysis show that, while in the two cements *B* and *E* rather more than half of the Na_2O and of the K_2O is retained in the new phase, in cement *D* much less, about 15 per cent, is retained, the quantities in this case being similar to those retained in normal C_3A in other cements. It seems, therefore, that sodium and potassium are not the only substituting ions which will produce the new phase. A large number of cations have been shown to be capable of replacing calcium or titanium in perovskite and giving either cubic or pseudo-cubic structures; in particular, replacements of the type $A^{II}(B^{II}_x B^{III}_y B^{V}_z)O_{2\cdot3-3\cdot0}$, where $x+y+z=1$, have been reported[4], which suggests possibilities such as $CaO(MgO_xAl_2O_{3y}P_2O_{5z})$ in cement.

The only unusual feature which the five cements have in common is a rather high MgO content; but as some MgO is detectable as periclase in the residues from selective hydrolysis, the presence of MgO in the chemical analysis cannot be taken as evidence of its presence in the 'perovskite' phase.

Tentatively, therefore, I conclude that the new phase must be regarded as a modified C_3A in which additional oxides, which may be Na_2O, K_2O, MgO or even Fe_2O_3 or traces of TiO_2, have lowered the symmetry from cubic to orthorhombic.

The X-ray evidence for the existence of the new phase is presented in Table 2. This evidence could not be obtained on a direct X-ray examination of the complete cement, only the line at $d=2\cdot71$ Å being distinguishable. The process of selective hydrolysis which was evolved is carried out in two stages. Acetic acid is added slowly, while stirring, to a 1·0 per cent suspension of cement in water, to maintain *p*H 4·5–5·0 for about 10 min. The residue is filtered off, washed with methanol and dried at 105° C. This treatment breaks down the silicate phases into products that are either soluble or amorphous, and no lines for these phases are detectable in the X-ray patterns of the residues.

A similar treatment at *p*H 3·5–3·8, for about 20 min, will leave only the ferrite phase, the quartz and some of the periclase unattacked.

Table 2 gives the observed *d* values and intensities (peak heights on diffractometer chart record) for a residue from the first stage (*p*H 4·5–5·0) of selective hydrolysis of cement *E*. The third column indicates to which compound each line may be attributed, lower case letters being used when the compound has only a very weak line at any *d* value.

It will be seen that most of the lines in the pattern which are not attributable to C_4AF match the patterns of NC_8A_3, and/or perovskite. The intensity relationship of the two lines at 2·72 and 2·695 is constant in the patterns of the residues from all five cements; this suggests that they are both produced by one material not by a mixture of C_3A and another compound. If this is the case then the six strongest lines of the new phase may be regarded as a splitting of the three strongest lines of C_3A: C_3A (440) at $d=2\cdot70$ (I = 100) becomes 2·72 and 2·695; C_3A (008) at $d=1\cdot908$ (I = 32) becomes 1·920 and 1·890; C_3A (844) at $d=1\cdot558$ (I = 24) becomes 1·564 and 1·550. This is characteristic of the change from a cubic to a pseudo-cubic structure, and it seems much more likely that the cement contains one lower-symmetry polymorph of C_3A than a mixture of C_3A with a material which closely resembles it both in composition and structure.

The immediate interest in the formation of this compound is that it renders measurement of the C_3A content of cements by X-ray diffraction more difficult, but its occurrence is of wider interest in the study of the high temperature phase chemistry of cements generally.

Examination of a number of cement clinkers suggests that the X-ray pattern described above is characteristic of the 'dark prismatic interstitial phase' which has been detected in some microscopic studies of polished clinkers. No clinker so far examined has shown either phenomenon without the other.

Table 1. Minor Element Content of Five Ordinary Portland Cements Found to Contain 'Perovskite' Phase

Surface Charge Density and Sorption of Water Vapour on Lithium Kaolinite

Keenan *et al.*[1] in an examination of adsorption of water vapour on several monoionic derivatives of kaolinite from Bath, South Carolina (Peerless No. 2, Vanderbilt Co., New York), found that—hysteresis being absent for all samples—lithium kaolinite showed the lowest water adsorption at any relative vapour pressure. Prior to the adsorption measurements (at 20° C), the samples were degassed under high vacuum at 70° C. Expressing the amount of water adsorbed per unit surface, these authors found identical values at any relative pressure for two samples of lithium kaolinite with different granulometric composition. They concluded that the adsorbed lithium ions have no effect on adsorption of water, and attributed this behaviour to the small ionic size of lithium, which permits the unhydrated ion to fit into the surface structure or to penetrate in the vacant octahedrally co-ordinated sites,

thus becoming sterically hindered from interaction with water vapour.

R. T. Martin[2], however, observed hysteresis in the water adsorption–desorption cycle on lithium kaolinite, prepared from a sample of clay with the same origin and submitted to the same pretreatment as in the work of Keenan *et al.* Moreover, this author ascribed the hysteresis to ionic hydration and deduced from loop scanning experiments that the hydration of lithium ions occurred from a relative pressure of 0·8 onwards.

J. J. Jurinak[3] investigated sorption of water vapour on kaolinite from Dry Branch, Georgia (Georgia Kaolinite Co.), and observed that the lithium-saturated sample, degassed under high-vacuum, exhibited reversible adsorption–desorption when the degassing temperature did not exceed 70° C. Like Keenan, Jurinak suggested absence of ionic hydration in lithium kaolinite.

In experiments carried out by me[4] on kaolinite from Whitehill, Plymouth, England (Continental China Clay, Brussels), the characteristics of which have been described previously[5], different monoionic derivatives (H^+, Na^+, Li^+, Ca^{2+}, Mg^{2+}) were also prepared and the isotherms determined at 20° C by a high-vacuum technique similar to that used by Keenan. Not only hysteresis was exhibited by all samples over nearly the whole relative pressure-range; but, whereas the general trend in succession of the isotherms was Li^+ kaolinite $< Na^+$ kaol. $< H^+$ kaol. $< Mg^{2+}$ kaol. $< Ca^{2+}$ kaol., the amount of water retained by the lithium derivative slightly outweighed the amount retained by the sodium one up to $p/p_0 = 0{\cdot}18$ in both branches of the adsorption–desorption cycle.

This behaviour can only be explained by assuming widely differing values in the binding energies of the lithium ions to the mineral lattice, one part of ions being so loosely bound that hydration occurs from low relative pressure onwards, another part being so strongly fixed that hydration—if occurring—only takes place at pressures near saturation.

That a single cation may be fixed by a clay mineral with a wide range of bonding energies is generally accepted[6] and can be accounted for with the aid of the following considerations: (1) The charge deficiencies on the mineral surface may originate from geometrically and energetically differing levels: substitution in the tetrahedral or in the octahedral layer, broken bounds around the edges, tetrahedrically co-ordinated aluminium[7], probably around the edges too. (2) If only, or predominantly, one mode of cationic binding is displayed by a particular clay mineral, for example, isomorphic substitution, a non-homogeneous distribution of negative charges may lead to local concentrations of adsorbed cations to the extent that repulsion forces become operative between them. Although a disturbance of the electrical neutrality in some part of the lattice must have a repercussion on the whole structure it is obvious that a cation repelled from the locus of positive charge deficiency should be less tightly held. It is logically premised that the probability of heterogeneous distribution increases with increasing charge density. When the negative charges are located around the edges (as is claimed by several authors for kaolinite) a high charge density will also induce interaction between ion-lattice attraction and ionic repulsion, especially if the ratio edge surface to planar surface of the particles is small.

Applying these considerations to dehydrated Li^+-kaolinite systems, it can be conclusively stated that the geometric and energetic status of the lithium ions versus the lattice and the subsequent behaviour upon contact with water vapour are ruled by the size and shape of the mineral particles, the nature of the charge deficiencies and, to a major extent, by the charge density. The different behaviour displayed by the lithium kaolinites in three of the four cases which are referred to should be understood in these terms.

The values of the surface charge density calculated on the four samples conform to the foregoing premises.

Absence of ionic hydration, resulting from a strong and probably single-valued Li^+-lattice binding energy, is observed on samples with a surface charge density of 0·6 (ref. 3) and 1·0 (ref. 1, fractionated sample) electronic charge per $m\mu^2$ respectively. For the lithium kaolinite undergoing ionic hydration at high relative pressure (ref. 2) and for which an average weaker binding energy has to be invoked, the value amounts to 1·3 $e/m\mu^2$. Finally, the strong heterogeneous distribution of Li^+ ions displayed by the sample of reference 4 corresponds to a surface charge density as high as 1·6 $e/m\mu^2$.

In situ Treatment of Kieselguhr for Gas Chromatography

The deleterious effects of adsorptive activity in supporting media for gas chromatography are well known; broad, long-tailed peaks are obtained, making area measurements in quantitative work more difficult, and obscuring small peaks due to impurities following a major peak. In so far as adsorptive activity may be due to metallic impurities, some amelioration is commonly effected by acid or alkali washing. However, the surface even of pure silica possesses active adsorption sites, presumably due to free OH groups, and several authors have indicated that adsorption due to this cause can be greatly reduced by treatment of the support with certain reactive silicon compounds.

The use of dimethyldichlorosilane for this purpose appears to have been first suggested in 1958 by Kwantes and Rijnders[1], and it has been used since by several other workers[2–4]. Since it is a difunctional compound, it would appear to be by no means ideal; if only one chlorine atom reacts with the surface of the support, a polar group still remains, while the reaction of both chlorine atoms requires a felicitous distribution of hydroxy groups on the original surface. Trimethylchlorosilane has been proposed for the same purpose by Kiselev[5], and would appear to be preferable, but hexamethyldisilazane, first proposed by Purnell[6], has become the most widely used reagent.

We have found that, although treatment by Purnell's method produces a marked improvement in the inertness of the column support, the friable nature of kieselguhr leads to the production of a considerable proportion of fines during the operation, the loss in weight on screening through a 100-mesh sieve amounting to 50 per cent. Moreover, fracture of the kieselguhr particles during sieving will, of course, generate new reactive surfaces.

It occurred to us that these disadvantages might be avoided by treatment of the column packing *in situ*. The procedure consists simply in injecting a small quantity of hexamethyldisilazane into the column at a temperature of 80° C, and with the carrier gas flowing at a reduced rate. A typical column 0·4 cm × 185 cm packed with 5 per cent 'Apiezon *L*' on kieselguhr requires an injection of 50 μl. of the reagent, at a carrier gas flow-rate of 5 ml./min. The reagent is eluted in about 4 min, whereupon the column is ready for use.

The effect in peak shape is illustrated in Fig. 1, which shows the peaks obtained with aniline on untreated and on treated columns.

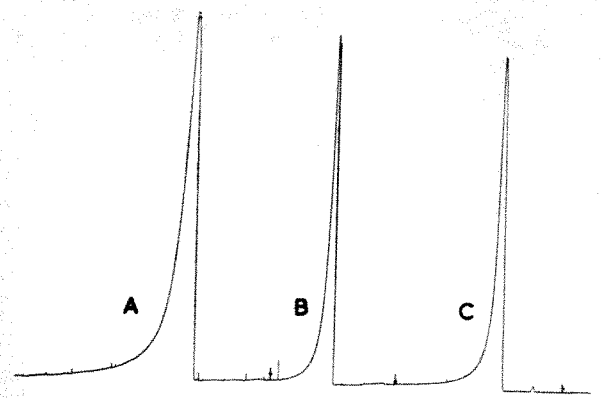

Fig. 1. Chromatograms obtained with aniline on packing prepared from (*A*), untreated 'Embacel'; (*B*), packing (*A*) treated *in situ* with hexamethyldisilazane; and (*C*), pre-treated 'Embacel'. Conditions: 0·4 cm × 185 cm column packed with 10 per cent 'Apiezon *L*' on 'Embacel', operated at 125° C with nitrogen carrier gas at flow-rate of 20 c.c./min; flame ionization detector

The superiority of the *in situ* treatment is more clearly indicated by a comparison of the ratio of peak height to width at 2 per cent of height. This ratio is 3·86 for the untreated column (*A*), 5·68 for the pre-treated column (*C*), but reaches the value of 9·18 for the column (*B*) treated *in situ*.

The *in situ* treatment of a more actively adsorbing support is even more striking in its effect. A column packed with 10 per cent 'Apiezon *L*' on 'Sterchamol' and operated under the same conditions as in Fig. 1 retained aniline and *o*-cresol indefinitely (more than 2 h); *in situ* treatment with hexamethyldisilazane allowed normal elution in 32 and 38 min respectively.

Naturally the new method can only be used when the stationary phase is itself free from polar groups, but this is not a serious limitation in practice, since adsorption by the support is less serious when a polar stationary phase is present; presumably the latter is preferentially adsorbed at the active centres.

Finally, the *in situ* use of hexamethylsilazane is also of value in reconditioning a column which has become contaminated with sample residues; such contamination often gives rise to a noisy baseline, and otherwise necessitates replacement of the column.

Electron Affinity of Tetracyanoethylene

The compound tetracyanoethylene (TCNE) has frequently been reported to be one of the strongest known Lewis acids. We have examined the electron affinity of TCNE using a modified form of the magnetron previously described[1].

A copious ion current was observed in the temperature-range investigations (1,500°–1,750° K), and at the lower temperature this ion current was some 20 times as large as the electron current. A preliminary analysis of the results indicates that the electron affinity is in the region of 150 kcal (6·5 eV). We attribute this extremely high value to the interaction of the electron with the octupole formed by the four cyanide groups.

This result is interesting in that the value found is greater than the work function of most metals. It is, however, to be stressed that the figure reported here is only a preliminary one, although it is correct as to order of magnitude.

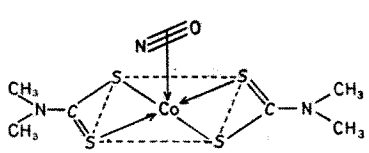
Five-Co-ordinate Compounds of Cobalt

Most complex compounds of cobalt are of oxidation state +3 and six-co-ordinate, or of oxidation state +2 and four- or six-co-ordinate. Until recently, only a few apparently five-co-ordinate complexes had been reported[1]. These were the anions $[Co(CN)_5]^{3-}$ and $[Co(CN)_5]^{2-}$, and the oxygen-carrying Schiff's base compounds (*A*) and (*B*).



(*A*)

(*B*)

Formula (*A*) shows the planar four-co-ordinate configuration suggested by Calvin *et al.*[2], but Diehl[1] believed that the true structure was five-co-ordinate with a water molecule bridging two cobalt atoms. However, tetrahedrally disposed bonds around the bridging oxygen atom would prevent the parallel arrangement of molecules of (*A*) deduced from X-ray evidence[2]. In addition, Ueno and Martell[3a] do not report any infra-red absorptions due to water in the compound and this is supported by other investigations[3b]. There is no direct proof that the secondary amino group in (*B*) is co-ordinated to the cobalt atom. The cobaltocyanide ion, in the solid state, has been found to be dimeric, with cobalt–cobalt bonds[4], and in aqueous solution is probably $[Co(CN)_5H_2O]^{3-}$. The compound first reported to be $Ag_2Co(CN)_5$ (ref. 5) is now believed to contain bridging cyanide groups[6]. So perhaps none of these compounds contains five-co-ordinate cobalt.

Many other five-co-ordinate compounds of cobalt have now been reported, but a detailed X-ray examination has been carried out only on nitrosyl(dimethyldithiocarbonato) cobalt (I) (ref. 7), which has the square pyramidal structure (*C*) with the N–O bond inclined at 139° to the pyramidal axis and forming an unsymmetrical π-complex with the cobalt atom.

(*C*)

Other apparently five-co-ordinate compounds are: $Co^{III}(PEt_3)_2Cl_3$ (ref. 8)*, $Co^{II}MeAs[(CH_2)_3AsMe_2]_2I_2$ (ref. 9*a*)*, $Co^{II}MeAs[(CH_2)_3AsMe_2]_2Br_2$ (ref. 9*b*)*, $Co^{II}(CNR)_5^{2+}$ (ref. 10), $Co^{I}(CNR)_5^{+}$ (refs. 10, 17), $Co^{I}(PR_3)_2(CO)_3^{+}$ (ref. 11), $Co^{II}Br_2[PH(C_6H_5)_2]_3$ (ref. 12), $Co^{II}X_2(CO)(PEt_3)_2$,* $Co^{I}X_2(NO)(PEt_3)_2$,* X = F, Cl, Br[13], Co^{I}(acetylacetone)$_2$(NO) (ref. 14)*, and $[Co^{III}$(8-aminoquinoline)$_2(NO)]X_2$ (ref. 15)*. Their likely configurations are square (or tetragonal) pyramidal, and trigonal bipyramidal[16]. Compounds marked with an asterisk have been assigned pyramidal structures. No detailed account of the first compound in the list has appeared, and the last is unusual in containing cobalt (III) and co-ordinated NO^-.

Compounds such as cobalt carbonyl hydride $HCo(CO)_4$ and its methyl-substituted derivative $CH_3Co(CO)_4$ (ref. 18*a*) are formally five-co-ordinate. In the former the carbonyl groups are tetrahedrally disposed with the H atom buried[18b] in the electron density of the metal and making little contribution to the stereochemistry of the molecule. Even the methyl compound appears to have essentially a tetrahedral configuration[18a].

We have found that compound (*A*) and several substituted forms (Table 1) will form mononitrosyls. These give non-conducting solutions in nitrobenzene, and molecular weight determinations show the parent, the 5,5′-dichloro, and the 7,7-dimethyl compounds to be monomeric in nitrobenzene. They have magnetic moments of about 0·5 Bohr magnetons at room temperature, and that of the 5,5′-dinitro compound increases linearly with $\sqrt{T}$. It therefore arises from temperature independent paramagnetism, no unpaired electrons are present, and electron pairing has occurred between the cobalt (II) atom ($3d^7$) and the NO molecule. From the magnetic results the compounds may be regarded as containing cobalt (III) and co-ordinated NO^-, or cobalt (I) and co-ordinated NO^+. However, their infra-red spectra show absorptions at the lower end of the range[19] ascribed to co-ordinated NO^+ (Table 1). These compounds are isoelectronic with (*C*), which has a similar nitrosyl absorption[20] at 1,626 cm^{-1}, and we believe them to be of the same structure. The planar nature of the parent compound would favour the formation of a square or, more accurately, tetragonal structure on five co-ordination.

Temperature-independent paramagnetism of the above magnitude could contribute largely to the fractional magnetic moment of 0·87 Bohr magnetons at room temperature reported for Co(acetylacetone)$_2$ NO. It is not necessary, then, to postulate[14] an equilibrium between a diamagnetic compound containing cobalt (I) and NO^+, and a paramagnetic compound containing cobalt (II) and neutral NO. The infra-red band at 1,675 cm^{-1}, typical of co-ordinated NO^+, indicates the former structure.

Table 1

Substituent	NO stretching frequency (cm^{-1})
None	1,624
5,5′-dimethyl	1,614
7,7′-dimethyl	1,618
3,3′-dimethoxy	1,634
5,5′-dichloro	1,638
3,3′-dinitro	1,667
5,5′-dinitro	1,696

The increase in the infra-red absorption frequencies with the substitution of electron-attracting groups (Table 1) shows that electron removal from the cobalt atom increases the N–O bond order, presumably by decreasing the extent of $d_\pi - p_\pi$ double bonding from the metal to the co-ordinated nitric oxide.

If no bridging water molecule is present in the parent compound (*A*) then the pyridine adduct of (*A*), and its oxygenated form in which an oxygen molecule bridges two cobalt atoms[2], contain five-co-ordinate cobalt. The oxygenated form has been considered to contain a peroxide bridge[2], but if the axis of the oxygen molecule were at right angles to the line joining the cobalt atoms to give a π-bonded complex, as has now been found for other cobalt compounds containing peroxide bridges[21], the bonding of NO and O_2 would be analogous. There is some evidence that this type of bonding occurs in the nitric oxide compound of hæmoglobin[22] and in oxyhæmoglobin[23].

The readiness of cobalt to form five-co-ordinate compounds can be related to the tendency of the metal to achieve (cobalt (I), $3d^8$) or approach (cobalt (II), $3d^7$) the effective atomic number of the next inert gas[24].

We have found that other Schiff's base complexes of cobalt (II), including the oxygen-carrying compound (*B*), will react with NO. This is also true for similar complexes of other transition metals, and we are investigating the nature of the products.

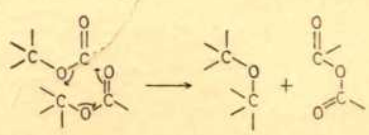
Thermal Decomposition of Certain Benzyl Esters

The early investigations of Hurd and Blunck[1] on the mechanism of the pyrolysis of esters have shown the existence of several decomposition pathways. In recent years, the degradation has been thoroughly examined, and the principal mechanism of the reaction has been shown to be a *cis* elimination[2]. However, at the present time, the nature of the secondary reaction mechanisms is not clearly understood.

An early investigation into the nature of these reaction pathways was reported by Hurd and Bennett[3] on the decomposition of benzyl benzoate. They indicated that the reaction affords toluene, benzaldehyde, benzoic acid, and benzoic anhydride. In recent years this ester and related compounds have been investigated by Jones and Ritchie[4]. They examined the decomposition at both 300° C and 500° C; the lower temperature pyrolysis gave results that were similar to those reported by Hurd and Bennett—however, the higher temperature pyrolysis gave complex decomposition products. Although details of the mechanism have not been postulated, both research groups have suggested that an ether intermediate may be involved in the reaction. In an attempt to isolate such an intermediate, the pyrolysis was examined at both 250° C and 675° C.

Benzyl acetate and benzhydryl acetate were pyrolysed in the following manner. The apparatus used for the decomposition consisted of an electrically heated 'Vycor' tube 28 cm long and 2 cm in diameter packed for a distance of about 20 cm with 'Pyrex' glass beads of about 6 mm diameter. The tube was heated to 675° C, and then 5 ml. of the ester was allowed to drop into the tube at a rate of about one drop per second. In the benzyl acetate experiment, the pyrolysate was analysed directly



by gas chromatography. The analysis was conducted at a column temperature of 195° C, 'Apiezon *L*' as the liquid phase, and a helium flow rate of about two bubbles per second. At these conditions three peaks were recorded that had retention times of 4, 8 and 26 min. These peaks corresponded to toluene (15 per cent), benzaldehyde (23 per cent) and benzyl acetate (62 per cent), respectively. The benzhydryl acetate products were analysed by elution chromatography (alumina). This analysis disclosed the presence of diphenylmethane (0·347 g), benzhydryl acetate (2·63 g) and benzophenone (0·401 g).

In an attempt to isolate intermediates in the decomposition, pyrolyses of benzyl benzoate and benzhydryl acetate were conducted at 250° C. The degradation was done in the following manner: 1 g of the ester was placed in a 'Pyrex' tube, and then the tube was heated to a temperature between 245°–250° C, and kept in this range for 24 h. The pyrolysate was then cooled to room temperature, dissolved in benzene, and chromatographed on alumina. In the benzyl benzoate experiment, a compound sublimed from the reaction mixture; this compound was identified as benzoic acid (0·120 g). Chromatographic analysis of the residue gave toluene and benzaldehyde (0·071 g; gas chromatography disclosed 40 per cent toluene and 60 per cent benzaldehyde), benzyl benzoate (0·016 g) and benzoic anhydride (0·045 g).

On chromatographic separation the benzhydryl acetate pyrolysis afforded diphenylmethane (0·220 g), benzhydryl ether (0·176 g), benzhydryl acetate (0·101 g), and benzophenone (0·193 g). Since the isolation of the ether was accomplished in the decomposition of benzhydryl acetate, the pyrolyses of benzyl benzoate and acetate were repeated. All attempts to isolate such an intermediate in the pyrolysis of these esters have failed. These results may be attributed to the instability of the ether under fairly low pyrolysis temperatures[5].

A low-temperature decomposition of fluorenyl acetate was also investigated in an attempt to isolate the ether. In this case, as in the benzyl ester experiments, the ether could not be isolated. The products that could be identified were fluorene (0·104 g), fluorenyl acetate (0·223 g) and fluorenone (0·128 g).

The formation of ethers and anhydrides in the decomposition may be easily explained in terms of a bimolecular elimination via a *quasi* six-membered intermediate:

The carbonyl and hydrocarbon components are formed from the breakdown of the ether[6]. This mechanism is also supported by the investigations of Coffin[7,8] on the decomposition of ethylidene acetate and related compounds. This pyrolysis affords the aldehyde and anhydride; the reaction mechanism has been postulated to be a concerted elimination[9].

ENGINEERING

Hydrostatic Extrusion

Bobrowsky and Stack[1] have suggested the possibility of using the hydrostatic extrusion process as a means of fabricating wire. That this is a proved fact is shown in Fig. 1. This shows five stages in the production of

Fig. 1

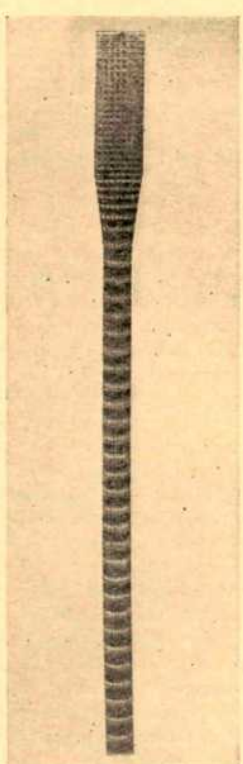

Fig. 2

aluminium wire from a ½-in. diam. bar. For illustration purposes in showing all reductions on one specimen, extrusion has been stopped at an earlier point on each successive pass, a fact which also points to the smoothness of this particular operation.

In their cold extrusion of aluminium, Bobrowsky and Stack found no irregularity on the back face of their partially extruded billet. This is typical of hydrostatic extrusion, and the fact that a state of homogeneous deformation exists until well into the die aperture is particularly evident in the specimen shown in Fig. 2. The photograph is that of the back end of a partially extruded long copper billet which has been split longitudinally and inscribed with a grid before extrusion in order that the flow pattern subsequent to extrusion may be observed. It will be seen that the transverse grid lines remain straight until about half-way into the die. Another interesting feature is that the uniform curvature of the grid lines across the extruded length indicates uniform mechanical properties throughout the product.

These experiments on conventional materials were part of incidental work supporting basic research into a high-pressure extrusion process at the Reactor Fuel-Element Laboratories, U.K. Atomic Energy Authority, Springfields, Preston, Lancs.

BIOCHEMISTRY

Release and Breakdown of Sialic Acid from Human Salivary Mucin and its Role in the Formation of Dental Plaque

Sialic acid is a constituent of human salivary mucin obtained by precipitating the mucin from saliva with either ammonium sulphate, weak acids, acetone or alcohol. Dried salivary mucin contains 2 per cent sialic acid[1]. In man, so far, the only sialic acid to be found from over a dozen different sources[2] has been *N*-acetylneuraminic acid (NANA), and it is reasonable to assume that it exists in this form also in human salivary mucin. Sialic acid, estimated as NANA by Svennerholm's method[3], is found in freshly collected, human, wax-stimulated saliva. There was a wide variation between different individuals and between the same individuals on different occasions. The mean of 40 determinations gave a value of 45 μg/ml. with a standard deviation of 12 μg/ml. and a range of 19–85 μg/ml. Dental plaque, however, which is believed to contain mucin[4], contained zero or trace amounts of NANA in over 40 determinations. The sialic acid must be lost from the mucin either when present in the saliva or else very rapidly during formation of the dental plaque.

Freshly collected saliva was incubated at 37° and the total and free sialic acid estimated at various times by the methods of Svennerholm[3] and Warren[5], respectively. The difference between these two values at any time represents the sialic acid that was still bound to the mucin. In over 30 samples of saliva the sialic acid was rapidly released and metabolized. In Fig. 1 is shown typical results obtained with pooled saliva during 6 h incubation. The addition of dental plaque up to a concentration of 2 per cent had no effect on the rate of release or breakdown of the sialic acid. After incubation for 24 h, only trace amounts of NANA were present in the saliva. NANA, when added to the saliva, was rapidly metabolized. Antibiotic ('Ledermycin', Lederle Laboratories) or heating in boiling water for 5 min prevented both the release of sialic acid and its subsequent destruction. It is concluded that the enzyme systems responsible for the release and breakdown of sialic acid from salivary mucin are bacterial in origin, are mainly present in the saliva, and correspond in action to the enzymes neuraminidase and aldolase, the action of which on other mucins and sialic acids respectively have been described elsewhere[2].

Addition of neuraminidase (receptor-destroying enzyme from *Vibrio cholerae*, Wellcome Research Laboratories) to either heated saliva or saliva containing antibiotic released the sialic acid from the mucin.

Dried salivary mucin contains 6 per cent hexosamine[1]. The hexosamine content of fresh saliva, estimated as glucosamine by the method of Boas[6], varied in a similar manner to NANA, there being a regular weight ratio of hexosamine : sialic acid of $3{\cdot}0 \pm 0{\cdot}3 : 1$. The metabolism of hexosamine was prevented by either antibiotic or heat, but on incubating fresh saliva alone for 24 h at 37°, 25 per cent of the hexosamine remained and some 90 per cent of this was not dialysable, indicating that it remained bound to some large molecule. In contrast to its content of sialic acid, dental plaque contains appreciable amounts of hexosamine. The mean hexosamine content of 13 samples of freshly collected plaque was 0·91 per cent with a mean deviation of 0·18 per cent. This corresponds to 3·5 per cent of the dry weight of the plaque. It is apparent that the sialic acid of the mucin is more amenable as a source of carbohydrate than is the hexosamine.

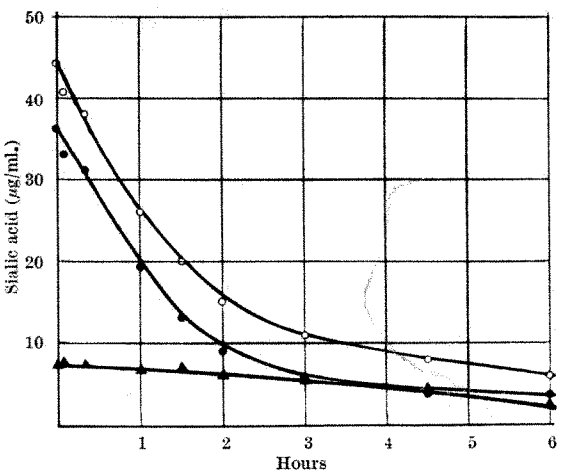

Fig. 1. Total (○), bound (●) and free (▲) sialic acid in human, pooled, wax-stimulated saliva on incubating at 37°

Gottschalk[7] has shown that the specific enzymatic release of sialic acid from ovine submaxillary mucin by neuraminidase causes the mucin molecule to change from a rigid rod form to that of a more random form without depolymerizing the molecule, and produces a concomitant decrease in the viscosity of the solution. It is tempting to speculate that a similar type of mechanism occurs in saliva, the viscosity of which decreases on standing unless arrested by enzyme poisons or penicillin[8]. There is very little direct evidence that the observed decrease in viscosity of standing saliva is due to depolymerization of the mucin, although this mechanism is extensively quoted[4]. The relationship, if any, between the sialic acid content of saliva and its viscosity is at present under investigation in this laboratory.

The strongly charged carboxyl groups of sialic acid (pK_a 2·6) impart a negative charge to the mucin molecule under all conditions that are experienced in the saliva. This charge is probably the main factor responsible for the low *p*H (*p*H 2–3) of minimum solubility of salivary

mucins[9]. The release of sialic acid from mucin should raise its *p*H of minimum solubility towards neutrality and under the conditions experienced in saliva would tend to cause the resultant mucin to precipitate out of solution. It has been found in this laboratory that there is a significant increase in the turbidity of saliva containing antibiotic on the addition of neuraminidase compared with a control saliva to which heat denatured enzyme has been added.

Reference to a typical oral organism that is known to produce neuraminidase could not be found in the literature. This may be because the enzyme is induced (adapted) by the organisms in the saliva because of the paucity of carbohydrate present. Recent work suggests that the neuraminidase of *Vibrio cholerae* is an induced enzyme[2]. Some indication that the enzyme is induced in saliva is shown by the fact that the sialic acid is released much more slowly from salivary mucin in the presence of an added 1 per cent buffered glucose. After 90-min incubation of fresh saliva containing glucose, the sialic acid content of the mucin was, in the majority of cases, more than 90 per cent its original value and in some instances over 50 per cent remained after 24 h incubation. This is in striking contrast to the results obtained in the absence of glucose (Fig. 1). The *p*H of the solutions in all instances were kept above 6 by the addition of phosphate buffer.

It is thought in this laboratory that the reaction involving the release of sialic acid from salivary mucin leading to its precipitation under mildly acid or neutral conditions plays an important part in the formation of dental plaque, and the lack of sialic acid and the presence of bound hexosamine in the plaque substantiate this view.

I thank Mrs. Mary Griffiths for assistance, Dr. A. J. Milne Gall and all members of the hospital staff who collected plaque and saliva, and the Medical Research Council for financial support.

Isolation of Phosvitin from the Plasma of the Œstrogenized Immature Pullet

The presence of phosphoprotein in the plasma of the laying hen is widely held to be the result of the action of œstrogenic substances produced by the growing ova of the mature bird[1], though the precise nature and quantities of œstrogenic substances present in the blood stream have not yet been determined. Recently it has been shown that the phosphoprotein in the plasma of the laying hen is phosvitin, the principal protein of egg yolk[2], and it seemed desirable to examine the plasma of œstrogen-treated non-laying birds to determine whether or not such treatments could, in fact, lead to the formation of phosvitin.

Immature pullets 12–14 weeks old were injected intramuscularly with œstradiol benzoate (2 mg/day) on alternate days for 10 days. During this time the plasma phosphoprotein concentrations increased markedly. The birds were then bled, the plasma collected and the phosphoprotein precipitated as the calcium complex before working up as described by Heald and McLachlan[2]. The partially purified fraction was further purified by stepwise elution from diethylaminoethyl cellulose with sodium chloride at *p*H 8·6[3]. Two main fractions containing phosphorus were obtained: a major fraction eluted with 0·30 M sodium chloride amounting to 54–60 per cent of the phosphorus, and a second fraction eluted with 0·25 M sodium chloride amounting to 30 per cent of the phosphorus added. The remaining 10–15 per cent of the phosphorus was found in minor fractions eluted with 0·15 M and 0·20 M sodium chloride respectively. The major fraction contained 9·5 per cent phosphorus and 9·75 per cent nitrogen, yielding a nitrogen/phosphorus ratio of 2·22. It contained 3·66 moles serine/10^4 g protein yielding a serine/phosphorus ratio of 1·0. These properties are identical with those of phosvitin from egg yolk[4] and from the plasma of the laying hen[2]. The second peak contained 6·3 per cent phosphorus and 10·9 per cent nitrogen, yielding a nitrogen/phosphorus ratio of 3·83. It contained 2·03 moles serine/10^4 g protein, giving a serine/phosphorus ratio of 1·0.

The results clearly establish that administration of œstrogen to the immature pullet results in the appearance of phosvitin in the plasma. Since, in birds of this age, the ovary is not developed and largely non-functional[1] the results also provide strong evidence that the synthesis of phosvitin takes place elsewhere in the body. The second component, which contains phosphorus and serine in a ratio indicative of their existence as phosphorylserine, was not found in any quantity in the plasma of the laying bird[2]. Since the immature pullet has no developing ova capable of removing plasma phosphoprotein for yolk formation it is considered that this second component is either an accumulated intermediate of phosvitin synthesis or a product of its breakdown.

Inhibition of Biological Synthesis of Acetylcholine by Triethylcholine

Bowman and Rand have suggested that the mechanism by which the triethyl analogue of choline causes failure of neuromuscular transmission is by interfering with synthesis of acetylcholine in the nerve endings[1]. If so, triethylcholine may be like HC-3 (hemicholinium), which has been found to inhibit the synthesis of acetylcholine by organized nerve tissue[2,3].

The experiments reported here were carried out to determine the effect of triethylcholine on synthesis of acetylcholine by sub-cellular fractions of rabbit brain homogenates.

The choline acetylase (acetyl-Co*A*: choline-*O*-acetyltransferase, EC 2.3.1.6) incubation system used was that described by Hebb, 1963[4]; acetyl-Co*A* is produced from acetylphosphate and coenzyme *A*, by phosphotransacetylase. The ACh synthesized was assayed biologically using the frog rectus abdominis muscle. Triethylcholine has been shown to be inactive on this assay preparation[1] and it was confirmed that triethylcholine does not affect contractions due to acetylcholine.

Table 1 shows the effect of triethylcholine on the synthesis of acetylcholine by the large granule or 'mitochondrial' fraction of rabbit brain (P_2 fraction) (ref. 4). When the concentration of choline (0·8 mg/tube) was optimal an equimolar concentration of triethylcholine (1·04 mg/tube) inhibited synthesis of acetylcholine by 11 per cent; doubling the triethylcholine concentration almost doubled the inhibition, and at the largest concentration of triethylcholine (10·4 mg/tube) the inhibition was 40 per cent.

Table 1. Inhibiting Action of Triethylcholine (TEC) on Synthesis of Acetylcholine by Mitochondrial Fraction of Rabbit Brain

Choline Cl Added to the system	Acetylcholine synthesized $\mu g/g$ $P2$ fraction	% inhibition produced by TEC 1·04 mg	TEC 2·08 mg	TEC 10·4 mg
0·2 mg	103	21	32	53
0·8 mg	195	11	20	40
3·2 mg	175	2·5	4·5	3·0

0·8 mg choline Cl equimolar with 1·04 mg TEC Cl. Final volume of system on incubation = 0·1 ml. enzyme + 0·5 ml. Pre-incubation mixture = 0·6 ml.

At a reduced concentration of choline (0·2 mg/tube) the same amounts of triethylcholine produced a greater inhibition of synthesis of acetylcholine. However, when the concentration of choline was increased 4-fold, triethylcholine had no significant effect on enzymatic synthesis of acetylcholine.

Treatment with ether is known to activate choline acetylase in brain homogenates[5], possibly by breakdown of membranes enclosing the enzyme. Comparisons have been made of the effect of triethylcholine on synthesis of acetylcholine by P_2 fractions before and after treating them with ether, which caused a 4-fold increase in the activity of the fraction (Table 2). The results show that while triethylcholine still inhibited enzymatic synthesis of acetylcholine the effect, expressed as a percentage, was much smaller than that obtained with untreated particulates.

Table 2. Inhibiting Action of Triethylcholine on Synthesis of Acetylcholine by Ether and Non-ether Treated Mitochondrial Fractions of Rabbit Brain

Choline Cl added	Acetylcholine synthesized ($\mu g/g$) $P2$ fraction: No TEC	TEC (4·16 mg)	% inhibition
No ether treatment 0·4 mg	108 μg	69 μg	36
Ether treatment 0·4 mg	438 μg	377 μg	14
Activity			

Ether treated : non-ether treated fraction—438 : 108, approx. 4 : 1.

Similar experiments using tissue slices obtained from rabbit caudate nucleus also demonstrated the inhibition of synthesis of acetylcholine by triethylcholine in the presence of low choline concentrations.

These results indicate that triethylcholine inhibits synthesis of acetylcholine more readily when the tissue binding of the choline acetylase is not disturbed and that the inhibiting action of triethylcholine can be antagonized by using higher levels of choline. This suggests that triethylcholine is acting like hemicholinium by competing with choline for access to the enzyme through some membrane. It may also possess a slight direct inhibiting action on choline acetylase since in ether-treated particulates synthesis of acetylcholine was still impaired to some extent by large concentrations of triethylcholine, although here again the inhibition could be overcome by increasing the choline concentration.

Taken as a whole the results described here provide an explanation of the effects of triethylcholine *in vivo* and support the hypothesis advanced by Bowman and Rand that this is due to impairment of synthesis of acetylcholine.

One of us (B. A. H.) holds a Medical Research Council scholarship. We thank Ward, Blenkinsop and Co., Ltd., for a gift of triethylcholine chloride.

Nucleotide Sequence Investigations in Microsomal Ribonucleic Acids of Normal and Rous Sarcoma Virus-infected Tissues

A characterization of nucleotide sequence in ribonucleic acids (RNAs) in tumours would be of importance to the understanding of the structure of these molecules in neoplastic tissues. Methods for the separation of mono- and oligo-nucleotides liberated with ribonuclease digestion by ion exchange chromatography have been developed[1] and applied to amino-acid acceptor RNAs with promising results[2]. This communication describes an investigation of some nucleotide sequences in microsomal RNA extracts from normal and Rous sarcoma virus-infected tissues. These are initial studies of a programme designed to analyse the structure of the nuclear and cytoplasmic RNA's of normal and tumour cells.

Chorio-allantoic membranes of 10-day old chick embryos were infected with 0·2 ml. of a $2{\cdot}5 \times 10^{-2}$ dilution of standard preparations of Rous sarcoma virus supplied by Dr. W. R. Bryan, of the National Institutes of Health. Eggs were incubated for 7 days, and tumour as well as normal membranes were afterwards collected. Histological examinations showed that virus-infected tissue contained more than 200 sarcoma cells for each normal cell present.

Tissue was homogenized in an ice-cold solution of 0·30 M sucrose and 0·001 M magnesium chloride with a 'Vir Tis 45' high-speed homogenizer. Nuclei, mitochondria and unbroken cells were separated by centrifugation at 8,500g for 15 min. Microsomal fractions were isolated by centrifugation at 105,400g (average) for 2 h. To extract RNA, pellets were suspended in 0·01 M potassium phosphate buffer, pH 7·0, containing 0·01 M disodium ethylenediamine tetraacetate (EDTA) and homogenized briefly at low speed. The solution was brought to room temperature, 0·5 per cent sodium lauryl sulphate was added, and stirred for 10 min. An equal volume of phenol (88 per cent) was then added and stirring was continued for 1 h. The preparation was centrifuged, the aqueous layer carefully pipetted off and the phenol extraction was repeated once more. Phenol was removed by shaking with ether at 2° C and ether was expelled by bubbling with nitrogen. The RNA was dialysed overnight (all dialysis tubing was pre-soaked in buffered 0·01 M EDTA for 2 days) against several litres of distilled water and vacuum-dried. RNA was determined by the Mejbaum orcinol reaction as described by Schneider[3]. Ultra-violet absorption spectra showed an average 260 mμ/280 mμ absorption ratio of 2·1 and 260 mμ/230 mμ of 1·6 for normal and tumour extracts.

Samples of RNA were resuspended in 0·01 M potassium phosphate buffer, pH 7·0, pancreatic ribonuclease (RNAse) was added (0·1 mg/mg RNA) with 1·0 per cent chloroform and the solution was incubated for 16 h at 37° C. The pH at the completion of the experiment was unchanged. Normal and tumour preparations showed the same rate of increase in optical density at 260 mμ with time and maximum values of 20–30 per cent increase. To separate nucleotide and oligonucleotide fragments, the digests were added to DEAE-'Sephadex' columns and eluted with ammonium carbonate. Mono- and oligo-nucleotides were identified by ultra-violet absorption spectra with pH changes[1]. The results are shown in Fig. 1. A comparison of the amount of material in each peak is given in Table 1. The last column of Table 1 indicates the degree of variation obtained in duplicate chromatograms of digests from tumour tissue RNA from an identical extraction where half the extract was chromatogramed a week after the other half. No gross differences in chromatographic pattern of RNAse digests of the normal and tumour tissue were detected. No significant changes were evident when the data were subjected to Friedman's rank sum test at the 30 per cent level. Fine differences in the amount of nucleotide in any given peak, which would be important biologically, probably cannot be detected in view of the

Figs. 1*a* and 1*b*. Chromatography of pancreatic ribonuclease digests of 3·3 mg of microsomal RNA from normal tissue (*a*) and 6·3 mg microsomal RNA from Rous sarcoma tissue (*b*). DEAE-'Sephadex *A*-25' (60 cm × 0·5 cm) exchanger was eluted with a gradient of increasing concentration of ammonium carbonate using a Varigrad. Region I, 100 ml. each of 0·01 M, 0·24 M, 0·01 M, 0·20 M, 0·20 M, 0·40 M, in six Varigrad chambers; Region II, 150 ml. each of 0·40 M, 0·50 M, 0·40 M, 0·90 M, 0·70 M in five chambers. Volume of fractions collected was 3·5 ml.

limits of analysis. Rous virus RNA, which is present in the microsomal RNA fraction from tumour tissue, is too small in amount compared to the cellular RNA to be detected in this analysis.

In view of the findings that RNA can induce differentiation and transformation in malignant cells[4–7], it is important to determine the structure of the various nucleic acids of malignant and normal tissues and to determine which, if any, have an altered base sequence. One may predict that the informational RNAs may be altered in tumours, although the functions of microsomal and parts of the nuclear RNA are still obscure. The results reported here show no significant differences in certain microsomal RNA base sequences of Rous sarcoma and normal tissues and depict the type of reproducibility that

Stimulation by Rat Liver Ribonucleic Acid of Incorporation of Amino-acid into Rat Liver Ribosomes

The discovery[1] that ribonucleic acid (RNA) and synthetic polyribonucleotides stimulated the incorporation of amino-acids into protein-like material in cell-free system from *E. coli* has been followed by many reports[2–6] of similar findings with systems from the same and other cells. Rat liver RNA was shown[5] to stimulate amino-acid incorporation when added to an *E. coli* system and rat liver RNA and polyuridylic acid caused increased incorporation of phenylalanine in a rat-liver microsomal system[6]. We wish to report that polyuridylic acid and rat liver RNA stimulate incorporation of amino-acid with rat liver ribosomes.

Table 1

	Ribosomes	C.p.m./mg protein
(*A*)	Prepared normally	
	Control	1,109
	+ RNA (exp. 1)	1,550
	+ RNA (exp. 2)	1,730
(*B*)	Prepared without salts	
	Control	488
	Pre-incubate 10 min	86
	Pre-incubate 10 min in presence of RNA (exp. 1)	382
	Pre-incubate 10 min in presence of RNA (exp. 2)	594
	Pre-incubate 10 min in presence of *s*RNA	74
	Pre-incubate 10 min + ^{14}C phenylalanine	164
	Pre-incubate 10 min in presence of 25 μg poly + ^{14}C phenylalanine	1,296

Rat liver RNA, prepared by the lauryl sulphate–phenol method[7], in the presence of bentonite[8] and in the cold to reduce breakdown of the RNA, caused stimulation (see Table 1) of incorporation of DL-(1-^{14}C)-leucine when added to a rat liver ribosomes system prepared as previously described[9]. When the ribosomes were washed and suspended in 0·05 M *tris* buffer *p*H 7·8 without added salts, instead of a medium containing salts, incubation at 37° for 10 or 15 min drastically reduced the ability of these ribosomes to incorporate amino-acids into protein when cell-sap, ATP, ^{14}C-amino-acid, GTP and sufficient salts were added to achieve optimal conditions[9]. The addition of RNA during the pre-incubation caused a greater percentage stimulation in the subsequent amino-acid incorporation and, in some experiments, stimulated the incorporation of amino-acids to above that shown by the ribosomes which had not been pre-incubated (see Table 1). Although the percentage stimulation was greater with the attenuated ribosomes, addition of RNA to ribosomes which had not been pre-incubated caused a greater absolute increase in the radioactivity incorporated.

It could be argued that the added RNA is protecting the ribosomes (or the soluble RNA (*s*RNA) subsequently added in the cell-sap) from breakdown by ribonuclease known to be associated with ribosomes[10]. We have, in fact, observed breakdown of added, labelled RNA during pre-incubation but it seems unlikely that all the effect of added RNA on amino-acid incorporation can be ascribed to protective action since we have observed that some preparations of RNA did not, for some still unknown reason, exhibit any stimulatory effect when added during incubation. We have also found that addition of 25 μg of polyuridylic acid to the ribosomes during pre-incubation caused a 6–8-fold stimulation of incorporation of phenylalanine into perchloric acid-precipitable material. It seems unlikely that such a small amount of synthetic polymer could exert much protective action.

It is also unlikely that the RNA added is causing stimulation because of the *s*RNA contained in it since addition of *s*RNA of equivalent amount to the stimulatory RNA used caused no stimulation of incorporation of amino-acid (Table 1).

A possible explanation of these results is that messenger RNA[11] (*m*RNA) exists in rat liver and is needed for incorporation to occur and that the added RNA contains *m*RNA. Pre-incubation may be removing messenger RNA from the ribosomes so that any added *m*RNA has a greater chance of sticking to the ribosomes, thus accounting for the greater percentage stimulation. Alternatively, pre-incubation in the absence of magnesium may have enhanced the ability of the *m*RNA added to combine with the ribosomes since, in the absence of magnesium, RNA will not form inter- and intra-molecular bonds.

Experiments are in progress to distinguish between the messenger and the protective function of the added RNA and to examine the properties of the stimulatory RNA.

We thank the Department of Scientific and Industrial Research for a maintenance grant for one of us (A. J. M.), the Medical Research Council for a grant, the Royal Society for a grant to purchase a counter, Mrs. B. Brown for her assistance and Prof. F. G. Young for advice.

Microbiological Dehydroxylation of Cholic Acid

The transformation of steroids by micro-organisms has been extensively applied to the steroid hormones and their derivatives[1]. More recently this technique has been extended to other compounds[2]. However, the dehydroxylation reaction of steroids by micro-organisms has not been reported.

In continuing our examination about microbiological degradation of bile acids[3], it was found that *Corynebacterium simplex* (I.F.O. 3530), cultured in a medium containing cholic acid as the sole source of carbon, produced 12α-hydroxy-3-oxo-$\Delta^{1,4}$-choladienic acid, which corresponds to the dehydroxylation derivative of cholic acid.

The following physical constants of the methyl ester of this acid indicated that this ester may be methyl 12α-hydroxy-3-oxo-$\Delta^{1,4}$-choladienate: $C_{25}H_{36}O_4$ (found: C, 75·11; H, 9·13); m.p. 146–148°; $[\alpha]_D^{23}$ +29·4 ± 2° (dioxane); $\lambda_{max}^{alc.}$ 246 mμ (ε = 15,400); $\nu_{max}^{CHCl_3}$ 3,481 cm^{-1} (OH), 1,732 cm^{-1} (ester) and 1,607, 1,624 and 1,663 cm^{-1} ($\Delta^{1,4}$-3-ketone). The identity with an authentic methyl 12α-hydroxy-3-oxo-$\Delta^{1,4}$-choladienate, prepared from methyl 12α-hydroxy-3-oxo-Δ^4-cholenate by selenium dioxide dehydrogenation, was determined by infra-red comparison and mixed melting point.

Micro Method of Haptoglobin Typing using Acrylamide Gels

The value of haptoglobin typing for human sera in relation to population investigations is well known[1]. The usual method of haptoglobin typing following electrophoresis on starch gels[2] is reliable but rather slow and cumbersome so that a quick and reliable method is of considerable advantage when large numbers of sera are to be examined.

The purpose of this communication is to describe a micro-method which utilizes electrophoresis in acrylamide gels on microscope slides and can be completed in 50 min. This method also offers a better resolution of haptoglobin types than the starch gel method and only 0·1 μl. of serum is required for examination. Recording of the results is done on photosensitive paper by trans-illumination of the slides in a condenser-type enlarger.

Microscope slides 75 mm × 25 mm are placed on a flat 'Perspex' tray the slides of which project uniformly 1·5 mm above the surface of the slides. A solution of acrylamide (supplied as chemical grout AM9 by Cyanamid. Australia Pty., Ltd.) of the following composition is prepared and is immediately poured into the tray.

AM9	7·5 g
Catalyst DMAPN	0·5 ml.
Ammonium persulphate	0·5 g
Water	to 100 ml.

The solution is then sealed from air with a flat 'Perspex' cover slid over the liquid. Polymerization occurs within 4 min at room temperature. The cover is then removed by sliding it off the gel and the gel is cut with a razor-blade along the edges of the slides, which are then immersed in a solution of *tris* (2-amino-2-(hydroxymethyl)-1 : 3-propanediol) of the following composition.

tris	9·2 g
Citric acid	1·0 g
Distilled water	to 2 l.

Sets of twelve slides are washed with 500 ml. of the *tris* solution for 6 h and then with a fresh 500 ml. of the solution overnight, following which the slides can be used, or left in the solution until required for use. The slides are placed in an open electrophoresis tank, as no special precautions are required to prevent evaporation, and

slits are made in the gel with a razor-blade 15 mm from the cathode end of the gel. After hæmoglobin has been added in the usual fashion[2] to the sera to be examined strips of cellulose acetate membrane or Whatman paper No. 1, approximately 1 mm × 5 mm, are immersed in the sera and after careful blotting are placed in the slits. The slides are then connected to the buffer tanks containing borate buffer *p*H 8·9, 0·0115 M, by filter paper wicks moistened with the buffer solution and are subjected to electrophoresis for 30 min at 20 V cm^{-1}. At the completion of the electrophoresis run the slides are immersed in the staining solution consisting of:

Saturated solution of 0-dianisidine (ref. 3) in ethanol	20 ml.
Ethanol	40 ml.
Acetate buffer, *p*H 4·6, 2·7 molar	20 ml.
Distilled water	60 ml.

After 10 min, 2 ml. of 30 per cent hydrogen peroxide are added for each 100 ml. of the staining solution and the slides are left for a further 10 min. The slides are then placed in tap-water for 30 min, after which they should be read or photographed within 12 h as the colour, although initially quite intense, gradually fades.

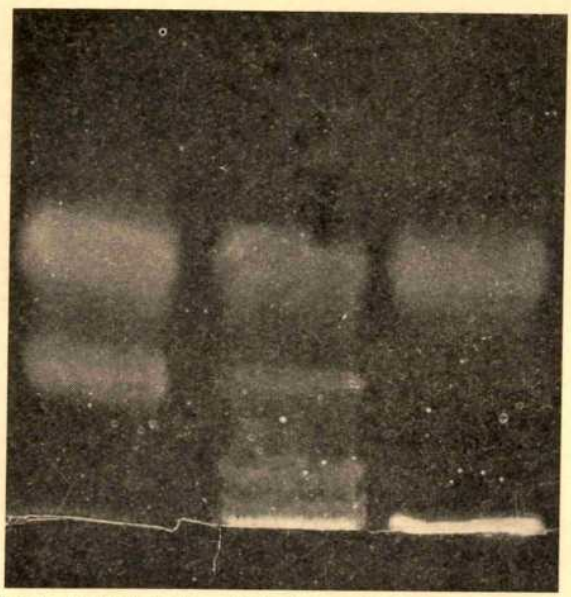

Fig. 1. Anode at the top of the photograph. Left to right: haptoglobin type 1–1, 1–2 and 2–2. Typing was confirmed by starch gel electrophoresis

With this technique the haptoglobin 1–1 band closely follows the hæmoglobin band, while the type 2–2 bands penetrate into the gel for only a short distance from the origin. The type 1–2 haptoglobin bands are particularly well displayed in the intervening zone. Because acrylamide gels are completely clear the contrast provided by the stained zones is extremely sharp. The extremely small amount of serum necessary to perform the analysis may have some importance in forensic applications of this method.

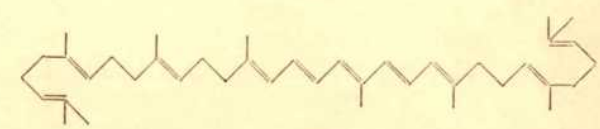
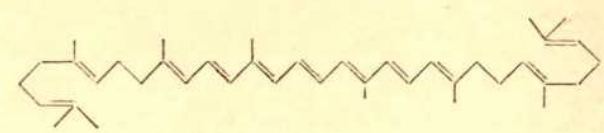
Comparison of the Reaction of *N*-bromosuccinimide with Phytoene and Lycopersene

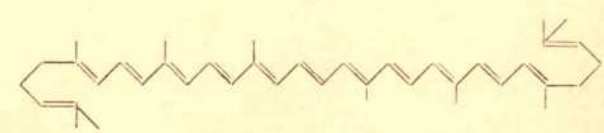
It is now well established that phytoene (I) is a precursor of the coloured carotenoids such as ζ-carotene and lycopene[1,2]. If the biosynthesis of carotenoids were exactly analogous to that of sterols then lycopersene (II), the 40-C analogue of squalene, would be the first 40-C precursor formed. The consensus of opinion is that this compound is probably not a naturally occurring material and is not a carotenoid precursor[1,3–5]; the opposite view is, however, held by Grob *et al.*[7,8]. Zechmeister and Koe[9] showed in 1954 that *N*-bromosuccinimide dehydrogenates phytoene to phytofluene (III) and ζ-carotene (IV), compounds now known to be intermediates between phytoene and lycopene (V). It was of importance to know what action *N*-bromosuccinimide, which imitates nature in its reaction with phytoene, would have on lycopersene under similar conditions.



In a typical experiment with phytoene (ex carrot oil) 20 mg were treated with *N*-bromosuccinimide according to the method of Zechmeister and Koe[9] for 8–10 min at 80–85° under carbon dioxide. The reaction mixture was chromatographed on a column of either CaO/'Celite' or alumina (Brockmann, grade V). In addition to unreacted phytoene, phytofluene and ζ-carotene were identified. Table 1 indicates the amount of each component formed; the phytoene unaccounted for must have been broken down in side-reactions; no trace of the unsaturated polyenes, neurosporene and lycopene, was obtained.



I



II

III

IV

V

Lycopersene (50 mg) was treated in the same way, and on chromatography of the reaction products, a number of slightly fluorescent zones were obtained; none of these exhibited the characteristic greenish fluorescence or absorption spectrum of phytofluene; furthermore, no coloured bands corresponding to ζ-carotene, neurosporene and lycopene were obtained. A red band was observed tightly bound to the top of the column; it did not have the characteristic appearance of a carotenoid; but it was eluted with ethyl acetate and examined

Table 1. Production of Phytofluene and ζ-Carotene from Phytoene by the Action of *N*-bromosuccinimide*

Compound	Amount (mg)
Residual phytoene	4·90
Phytofluene	0·44
ζ-Carotene	0·045

* Reaction carried out according to ref. 9.

spectrophotometrically. It showed only general absorption in the visible region of the spectrum and no bands characteristic of carotenoids.

Because it was possible that lycopersene reacted more rapidly with *N*-bromosuccinimide than phytoene did, the experiment just described was repeated and samples of the reaction mixture were taken at 10-min intervals over a period of 1 h. These samples were then examined by thin-layer chromatography with 'Kieselgel *G*' as adsorbent[3-5] and light petroleum (b.p. 40–60°) as developing solvent; markers of lycopersene and phytoene were always included as references. The positions of the spots after development were revealed by exposing the plates to iodine vapour when compounds possessing unsaturated centres are revealed by a brown stain[4,5]. In no case could a spot corresponding to phytoene be obtained, although the method employed would reveal the presence of 0·50 μg of this compound. A large spot corresponding to unchanged lycopersene was observed in every case.

The results indicate that under the experimental conditions which allow the conversion of phytoene into phytofluene and ζ-carotene by *N*-bromosuccinimide, lycopersene is not dehydrogenated to phytoene.

We thank Prof. B. C. L. Weedon for a gift of phytoene isolated from carrot oil and Dr. O. Isler, Hoffman–La Roche, Basle, for a gift of synthetic lycopersene.

Synthesis of an Aromatic Ring in Insects

It is now generally accepted that oxidation products of aromatic compounds are involved in the hardening of the skeletal proteins of insects[1]. The strong circumstantial evidence that, in blowfly larvæ, tyrosine gives rise to 'tanning' phenols[2] has recently been substantiated by the finding that injected tyrosine labelled with carbon-14 is converted to *N*-acetyl-3,4-dihydroxyphenylethylamine, the natural tanning agent of *Calliphora*[3].

In the cockroaches, *Blatta* and *Periplaneta*, 3,4-dihydroxybenzoic (protocatechuic) acid, after oxidation, serves to harden the proteinaceous egg capsule[4]. This dihydroxyphenol is produced in relatively large amounts. It has been shown that it is secreted by one of the sexual accessory glands—the left colleterial gland—in the form of the 4-O-β-D-glucoside[5]. This stable precursor is enzymatically hydrolysed at the time of egg-laying to give free protocatechuic acid, which is then oxidized to its quinone[6]. In view of the importance of 3,4-dihydroxyphenols to insects, and the sparsity of information as to their origins, a preliminary attempt has been made to discover the metabolic pathway to protocatechuic acid. In the main this has involved injecting substances labelled with carbon-14 which could be suspected of being metabolic precursors of protocatechuic acid, and afterwards assaying egg-capsules and colleterial gland for radioactive protocatechuic acid and its precursors.

In order to examine the possibility that synthesis of protocatechuic acid would occur from tyrosine, the aromatic ring remaining intact, approximately 0·4 μc. uniformly labelled tyrosine carbon-14 was injected into female cockroaches (*Periplaneta americana* (L.)) which were due to start egg-laying within two days. After egg-laying had taken place, extracts of the egg capsule, run as partition paper chromatograms, in butanol/acetic acid/water, 4: 1: 1, indicated that a radioactive substance was present corresponding with protocatechuic acid. Conversion of tyrosine to this substance was in excess of 6 per cent. Likewise, if left colleterial glands were assayed 24 h after injection, a substance corresponding with the glucoside of protocatechuic acid was strongly radioactive. After injection with tyrosine-α-carbon-14, no radioactive protocatechuic acid was detectable in egg-capsules.

These results can be interpreted as indicating that tyrosine is converted in the insect body to protocatechuic acid, and that partial degradation of the side-chain occurs.

In a second set of experiments, 1 μc. glucose-1-carbon-14 was injected into cockroaches. It was afterwards found that, not only was the glucoside, as would be expected, radioactive, but also free protocatechuic acid.

The attribution of radioactivity to protocatechuic acid and its glucoside was based on the detection of radioactivity in appropriate positions on partition paper chromatograms. For added support, the substances were eluted and run in a second solvent. A further elution was carried out, and the free acid esterified with methanol; the R_F value of the ester corresponded with authentic methyl ester of protocatechuic acid. In addition, the suspected protocatechuic acid, from animals that had received injections of glucose-1-carbon-14, was eluted from the chromatogram and co-crystallized with authentic protocatechuic acid. After three crystallizations the product retained its specific activity, while specific activity rapidly fell off at each recrystallization with *p*-hydroxybenzoic acid. Protocatechuic acid derived from the glucoside by acid or enzymatic hydrolysis behaved in the same way.

The evidence shows that both tyrosine and glucose can serve as precursors of protocatechuic acid, but the metabolic pathways appear to be distinct. Inasmuch as glucose can give rise to protocatechuic acid, and since tyrosine can, after ring-cleavage, be used in part to form glucose, a pathway from tyrosine to protocatechuic acid by way of glucose is conceivable; but were this the case, the conversion ratio from glucose to protocatechuic acid would be expected to be greater than (certainly not less than) the conversion ratio from tyrosine. The latter is, however, ten times the former. It appears, thus, that protocatechuic acid can be synthesized by two independent routes: (*a*) directly from tyrosine; or (*b*) from glucose.

The conversion of glucose to aromatic compounds by several paths is known to occur in micro-organisms and plants. One pathway involves condensation of acetates to form the ring[7], but does not lead to benzene compounds hydroxylated in the 3 and 4 positions; another, however, involving condensation of phospho-enol-pyruvate with erythrose-phosphate is known to lead to synthesis of both tyrosine[8] and protocatechuic acid[9]. It can be reasonably supposed that the second of these is the one involved in insects. At the time of these experiments there was no report of the ability of a metazoan to synthesize an aromatic ring, but there is evidence now that perhaps such a synthesis occurs in nematode worms[10], and there is circumstantial evidence that it must occur in echinoderms[11].

It appears possible that the glucose pathway to aromatic compounds in cockroaches is a result of the activity of symbiotic micro-organisms: there is some corroborative evidence, for example, mealworm beetles freed of their symbionts have a lighter coloration than normal[12], which could be taken to indicate that dietary aromatic compounds are insufficient and must be supplemented by symbiotic products before an adequate amount of phenolic pigment can be synthesized. It is interesting to find that, with one exception, all investigations of the dietary requirements of insects have included as essential either tyrosine or phenylalanine[13]: the exception is the case provided by the cockroach *Blatella* which is closely related to *Periplaneta*. Unfortunately, no information about the requirements of *Periplaneta* is availale.

PHYSIOLOGY

Behaviour of Lysosomes in Hæmorrhagic Shock

In a series of detailed publications[1–5], Fine *et al.* have maintained that the probable cause of death in traumatic shock is the irretrievable collapse of the circulation caused by a bacterial toxin which intensifies vasoconstrictor activity so as to injure the splanchnic viscera, with resulting decline in vascular reactivity to catechol amines and functional damage in key organs, especially the liver and intestine. In the absence of any obvious systemic or local infection, these workers have considered that the most likely source of the toxin is an endotoxin derived from the intestinal flora. The difference between that type of shock which responds to resuscitative measures, that is, 'reversible shock', and the irreversible form would appear to depend on the ability of the reticulo-endothelial system, particularly in the liver and spleen, to inactivate this toxin. This ability declines if the animal is in shock for 2 h or longer. There are indications that this detoxication process is concurrent with an esterase-like protein in spleen and liver that releases phosphate. Abolition of vasoconstrictor activity in the splanchnic area by cœliac blockade preserves this process as well as the vascular integrity of the portal and systemic circulation. Under these circumstances the animals are able to survive an otherwise lethal exposure to shock. It is noteworthy, however, that while functional differences in the spleens and livers of normal and shocked animals have been observed, no histological abnormalities have been detected.

It appears, therefore, that the prime cause of traumatic shock is a defect in the detoxicating powers of the reticulo-endothelial system. It has been shown recently that the lysosomes do not act merely as 'suicide particles', but show reversible 'activation' indicative of a physiological function in cellular detoxicating mechanisms[6,7]. Moreover, not only is the characteristic enzyme of these particles an acid phosphatase, but also the apparent activation, and even liberation, of the enzyme has been found to be a very early concomitant of the shock of operative trauma[6].

It seemed reasonable, therefore, to examine the condition of the acid phosphatase in lysosomal particles in the spleen of rabbits subjected to both reversible and irreversible hæmorrhagic shock. This has become possible in tissues because of the development of the controlled temperature freeze-sectioning procedure[8] and of a modified procedure for this enzyme[10]. The preparative procedure has been shown not to alter the permeability of the lysosomal membrane to β-glycerophosphate which was used as the substrate, so that apparent activation of this enzyme within the particle can be detected. In the histochemical method the lysosome is subjected to a degree of disruption so controlled as to modify the membrane of normal lysosomes only sufficiently to yield a weakly positive particulate reaction (the fragility test of Bitensky[7]). If the lysosomes have become 'activated' by the previous conditions within the body, the membrane will be less capable of withstanding this degree of disruption and a strong reaction will ensue, possibly with some diffusion of stain out of the particles. With more extreme *in vivo* damage, the controlled degree of disruption may produce either diffuse staining or even complete loss of staining due apparently to release of the enzyme from the particles into the cell, or even entirely out of the section.

A study has now been made in which the condition of the acid phosphatase in the spleen of normal rabbits and of those subjected to reversible or irreversible hæmorrhagic shock has been investigated. For the reversibly shocked animals, rabbits were exposed to severe hæmorrhagic shock for up to 2 h; some were resuscitated by being transfused with all their shed blood and were observed for up to a further 2 h to ensure the reversibility of this condition, while others were killed immediately. For irreversibly shocked animals the time of exsanguination was prolonged for at least 6 h, after which time they were shown not to respond to treatment. Sections were prepared by the freeze-sectioning procedure and stained for acid phosphatase by the method described by Bitensky[10].

The fragility test performed on sections of spleen from normal animals demonstrated that acid phosphatase was contained within discrete particles in large cells of the pulp which appeared to be macrophages. In their response to acid conditions, and in the behaviour of the enzyme, these particles corresponded to lysosomes[9]. In all the rabbits subjected to reversible hæmorrhagic shock these particles were more fragile. Thus, for a given incubation period, they showed greater apparent activity for acid phosphatase than did normal particles, or were even disrupted by the incubation, allowing local diffusion of the reaction. However, in each of a series of experiments, the effect in the animals in irreversible shock was more extreme, varying from considerable diffusion of the reaction to almost total loss of staining.

The ability of lysosomal enzymes to perform a physiological, as distinct from a 'suicidal', role in the cell must depend on the structural integrity of the organelles. Toxic conditions have been shown to cause such reversible modification of this membrane as to increase its permeability, as evinced by this intraparticulate response to β-glycerophosphate, without necessarily permitting the escape of the enzymes[6,11]. It has now been shown that in the spleen of rabbits subjected to reversible hæmorrhagic shock, the membrane of these organelles is indeed so modified. However, in the animals suffering irreversible hæmorrhagic shock, the altered location of the acid phosphatase indicated disruption of the structural integrity of these organelles. Hence, it has been shown that one difference between the reversible and irreversible condition of hæmorrhagic shock is the change in the state

of lysosome-like particles in the large cells of the pulp of the spleen, as would be indicative of a breakdown in the ability of such organelles to function in detoxication.

It may thus be permissible to speculate as follows: it is known that many conditions, including the trauma of surgical operation, cause modification to lysosomes[6,7]. Moreover, lysosomes seem to have some role in the detoxicating mechanism of normal cells[7]. It has now been shown that the condition of irreversible shock may be characterized by the disruption of lysosome-like particles. Thus, it seems conceivable that the primary effect in irreversible hæmorrhagic shock is loss of the integrity of lysosome-like organelles. Consequently they can no longer detoxicate endotoxin, which is thus able to circulate and affect vital sensitive target organs in the body.

Without the courteous assistance of H.M. Customs, this collaborative study would not have been possible.

Assessment of Functional Competence in Isolated Muscular Tissues

In order to test for functional competence in thin pieces of isolated tissue containing muscular elements, such as the skin of the rat (which contains smooth muscle and a sheet of skeletal muscle known as the panniculus carnosus), a bath was devised in which the muscles could be excited directly or indirectly by transmural stimulation[1]. The response of the stimulated muscle provided a measure of functional competence in the surviving tissue. This bath and also our method of recording the pressure changes developed in it are described here.

A circular piece of the tissue under investigation was first cut out and then clamped between two 'Perspex' rings to form a diaphragm. To achieve rigid clamping of the tissue between the rings, the upper surface of the lower and the lower surface of the upper ring were lined with glass paper. This assembly was then placed on a thin rubber washer in the small 'Perspex' bath specially made to accommodate it (Fig. 1). The bath was made in two sections, the lower half with an internal ledge on which the rings rested and an internal thread above the ledge and the upper half with an external thread so that it could be screwed into the lower and would thereby serve to hold the rings and the tissue firmly in place. This created an upper and a lower compartment separated from one another by the tissue; both compartments were filled with Krebs's solution (of the following composition in g/l.: sodium chloride 6·9; potassium chloride 0·35; potassium dihydrogen phosphate 0·16; crystalline calcium chloride 0·37; crystalline magnesium sulphate 0·29; glucose 1·0 and sodium bicarbonate 2·1) and a coiled platinum electrode projected into each.

The upper compartment (approximate capacity 10 ml.) was connected with a reservoir containing Krebs's solution which could enter this compartment at controlled rates: the solution in both this compartment and the reservoir was bubbled continuously with 95 per cent oxygen: 5 per cent carbon dioxide. Although continuous oxygenation was provided only through the Krebs's solution of the upper and not the lower compartment, the results have shown that this was sufficient to prevent any deterioration of response in thin muscular tissues such as rat diaphragm or rat panniculus carnosus over a period of hours.

The lower compartment (approximate capacity 2·5 ml.) was also filled with Krebs's solution and was connected to another reservoir, the height of which could be varied. Adjusting the height of this reservoir changed the pressure in the lower compartment and on the under surface of the tissue diaphragm. When the reservoir was raised above the level of the bath, positive pressure was applied to the lower surface of the tissue and pushed it upwards into the shape of a dome. This had the effect of stretching the fibres and thus putting a load on the tissue; the extent of the load depended on the height of the reservoir. Very little load (reservoir heights of 5 cm or less) was required to give maximal contractions. Transmural stimulation flattened the dome as the muscular elements contracted and increased the pressure in the lower compartment.

Changes in pressure in the lower compartment were transmitted to the diaphragm of a variable reluctance pressure transducer which was connected to the compartment by means of a small glass funnel, the rim of which just fitted over the circumference of the transducer, and

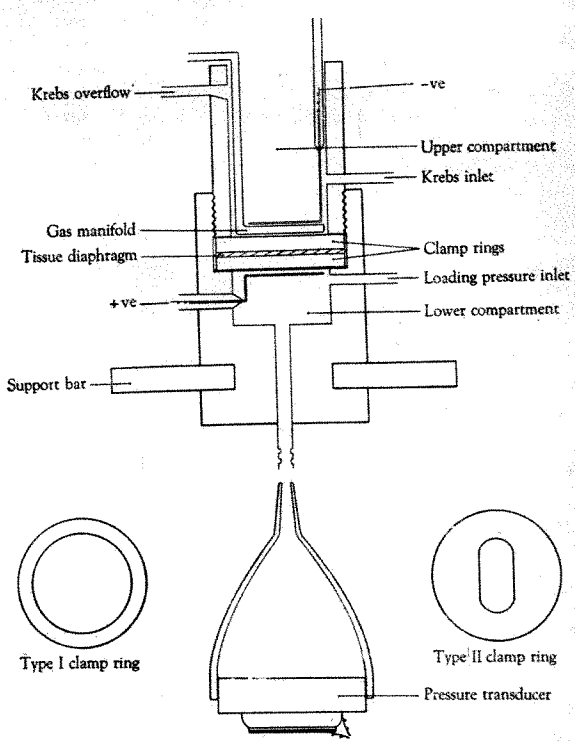

Fig. 1. Diagram of bath assembly with tissue-diaphragm in place ready for stimulation. Type I clamp rings are for tissues which can be obtained in adequate amounts; where less is available Type II clamp rings may be used

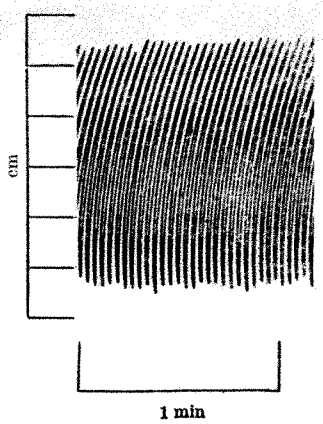

Fig. 2. Record of pressure fluctuations produced by contractions of the rat panniculus carnosus preparation as the tissue-diaphragm. Stimulation with supramaximal square-wave shocks of 0·04 msec duration. Frequency 0·5 c/s. Pen recorder

the stem was attached by polythene tubing to the lower compartment. The whole system, lower compartment, the connecting tube and funnel were filled with Krebs's solution so that pressure changes in the lower compartment were transmitted via the fluid in the system to the transducer.

The transducer formed one arm of an a.c. bridge the output from which was amplified, demodulated and recorded on a moving-coil pen recorder. Rapid fluctuation of pressure corresponding to the contractions and relaxations of the tissue-diaphragm and giving one full-scale deflexion per sec were well seen in this way (Fig. 2), though slower changes, such as those resulting from smooth muscle contraction, gave less satisfactory records.

This system of sensing pressure changes is essentially similar to that using differential inductive pressure transducers. We have also used these transducers in conjunction with an ultra-violet recorder (New Electronic Products, Ltd.), and with this method of recording excellent results were obtained with both slow and fast contractions. The great sensitivity and speed of recording of this method showed that with the rat panniculus carnosus preparation[2] the relaxatory phase was not merely the mirror image of the contractile phase as we had been led to suppose from pen recordings, but showed two distinct waves along its course. These are more fully described elsewhere[2].

The temperature of the solution in the upper compartment was controlled by running the Krebs's solution through glass coils in a constant-temperature water bath.

Transmural stimulation with coaxial electrodes[3], mostly of guinea pig ileum, has been fairly widely used since it was introduced by Paton, but coaxial disposition of electrodes can only be used in tubular tissues such as intestine or those which can be prepared as tubes such as tail skin[4,5]. The method described here permits application to a wider variety of problems.

We thank Dr. J. E. Gardiner (Royal College of Surgeons) for advice and Mr. S. Askill for the machining of the bath.

Biomicroscopic Observations on Vasoconstrictive and Thrombogenic Effects produced by Long-chain Saturated Fatty Acids within the Vasculature of the Wing of an Unanæsthetized Bat

Poole[1] reported in 1955 that when certain fatty acids in low concentration are added to plasma the clotting time is shortened. In 1959 he[2] modified Chandler's[3] system to make and to study artificial thrombi. In 1961, with Connor[4], he showed that when straight-chain saturated fatty acids with 16 or more carbon atoms were added to mixtures of blood in Chandler's system thrombus formation was accelerated and the thrombi so formed larger. Short-chain fatty acids, C_6 and C_7, had no activity and unsaturated acids were inactive, or very nearly so.

That these *in vitro* effects occur *in vivo* were shown by Connor[5] and Soloff and Day[6], who found massive arterial and venous thrombosis in dogs after a single intravenous infusion of palmitic or stearic acid.

Soloff and Day found that dogs which survived infusions of the saturated fatty acids had shorter silicon clotting, recalcification, and stypven times and lower platelet and polymorphonuclear cell counts than those dogs given unsaturated fatty acids. Kaolin produced thrombi and death similar to that seen after infusions with saturated fatty acids.

However, they could not obtain blood for coagulation studies from the dogs which died because the needle almost invariably became impaled upon a clot or upon gelatinous-like blood.

In an attempt to visualize the dynamic morphological changes culminating in thrombosis produced by intravascular injections of fatty acids, we have used Nicoll and Webb's[7] technique to examine the vasculature in the wing of the unanæsthetized bat.

As little as 0·01 c.c. of 0·01 per cent suspension of the sodium salt of stearic or palmitic acid injected into a major artery or vein in the unanæsthetized bat's wing produced unique vascular effects and thrombogenic effects which cannot be duplicated by much larger volumes of oleic or linolenic acid, inorganic solutions of comparable *p*H, glucose, saline or kaolin in concentrations of 0·001–0·1 per cent. Even amounts of kaolin sufficient to cover the entire circumference of the intima and occupy half the length of the major vessel and reduce its lumen to one-half or less fail to change the normal flow and characteristics of the bat's blood.

Immediately after the initial flush, saturated fatty acids injected intra-arterially produced an intense arterial vasoconstriction and thrombi. Palmitic acid appears to produce a more widespread vasoconstriction but the general characteristics of the vasoconstriction are identical for both substances. On the other hand, stearic acid is more thrombogenic.

Vasoconstriction is diffuse and occupies both the major vessel and all its branches and occasionally vessels other than those injected. Superimposed upon this diffuse constriction are more intense focal constrictions which have no recognizable relationship to architectural differences in the character of the vessel. It is, of course, possible that these focal constrictions may be at the origin of the vaso vasorum. The combination of diffuse and superimposed focal vasoconstrictions gives the vessel a unique appearance. When multiple focal constrictions are present, the artery may assume a beaded and rarely a violin-like shape. Vasoconstriction may persist for several hours to as long as several days (in one bat for 11 days). During this time, vasoconstriction may remain unaltered or wax and wane slightly due to vasomotion. Both the diffuse and focal constrictions are independent of nervous control because they can be produced in the denervated vessel. However, part of the persistence of the vasoconstriction is under nervous control because constriction that has persisted for hours or

days can be partly released by sectioning of the arterial nerve supply.

Blood within the constricted vessels oscillates back and forth except in that region where an unobstructed branch permits its exit.

At the same time, platelet thrombi are seen in the major arterial vessel and its branches. They are usually small and are quickly swept through the A/V pathways into the major vein and finally out of the field of vision. Some platelet thrombi may become adherent to the inner surface of the arterial wall. These adherent platelet thrombi most commonly are situated at the origin of bifurcations of the major vessels or their branches. These adherent platelet thrombi may persist for hours or days. Some platelet thrombi develop tails of white- and red-cell aggregates or such aggregations may surround the free margins of the platelet thrombi. Similarly, platelet thrombi which are swept into the major vein may also become adherent to the venous wall. Platelet thrombi in the vein may be much larger than those seen in the artery. An occasional platelet thrombus may be actually 2–3 times the diameter of the constricted artery. This large size is partly due to impaction of platelet thrombi on others upstream. Platelet thrombi, therefore, enlarge not only by aggregation of individual platelets, but also by embolization of one platelet thrombus on another. A platelet thrombus which is adherent to the internal surface of the vascular wall is rocked back and forth until it is finally, after hours or days, dislodged and swept forward again either to disappear into the central circulation or to join platelet thrombi upstream.

However, when the thrombus obstructs flow or when blood oscillates back and forth within the constricted vessel, white and red cell tails may also develop.

It is noteworthy that many more white blood cells are seen adhering temporarily to the vascular endothelium after an injection of an unsaturated fatty acid than after the injection of a saturated one, even after its vasoconstrictive effects have disappeared.

Intravenous injections of saturated fatty acids do not produce the vasoconstrictive effects seen after arterial injection. Platelet thrombi are, however, produced and are both more abundant and larger. When the platelet thrombus is large enough to obstruct or almost completely obstruct the lumen of the vein, the collateral circulation enlarges and takes over the flow of blood. These platelet thrombi may also develop a white and red cell tail.

Heparin prevents both these vasoconstrictive and thrombogenic effects.

The fact that saturated fatty acids are thrombogenic in the living dog and bat suggests that this property is common to the mammalian species and tends to unite Duguid's[8] hypothesis that atherosclerosis is a transformation of thrombosis with the more commonly accepted hypothesis that atherosclerosis is a fault of fat metabolism[9]. However, this work indicates that saturated fatty acids also produce vasoconstriction of arteries. This effect may be equally or more important than its thrombogenic effect in the etiology of atherosclerosis, which is an arterial disorder.

All biomicroscopic observations are being documented by cinephotomicrography.

HISTOCHEMISTRY

Histochemical Demonstration of Monoamine Oxidase in the Earliest Phase of Wound Healing

A dynamic pathological process, such as the local response to injury, brings about the production of numerous substances by the injured cells. According to the prevalent view, directly vasodilative forces are augmented in the inflammation (for example, leucotaxin[1] or histamine[2]). To the best of my knowledge there has been no previous report of the other possible mechanism, inactivation of vasoconstrictive factors. The latter could indirectly contribute to the vasodilatation.

Monoamine oxidase deaminates serotonin (5-hydroxytryptamine), released by platelets[3]. In addition, catecholamines are involved. An increase in monoamine oxidase activity might, thus, lead to a decrease in these vasoconstrictive substances.

In the present experimental investigation on 27 male albino rats, circular skin wounds, 5 mm in diameter, were cut in a shaved dorsal area. The skin inside the circle was excised and the wounds were neither sutured nor dressed. The animals were decapitated at intervals of 1, 2, 4, 8, 16, 24, 48, 72 and 96 h after the injury. Skin flaps containing the wounds were removed immediately and frozen with isopentane, chilled to $-70°$ C.

Sections were cut in a cryostat at 20μ, incubated for 60 min at $+37°$ C in a solution described by Glenner[4], and further processed according to his method. Tryptamine was used as the substrate in all experiments, but in place of 'Nitro-*BT*', '*TNBT*' (2,2′,5,5′-tetra-*p*-nitrophenyl-3,3′-(*p*-biphenylene)-ditetrazolium chloride[5], Dajac Laboratories) was used as an electron acceptor in alternate sections. For controls, phenylhydrazine hydrochloride (0·01 M) served as a specific inhibitor of monoamine oxidase. In addition, alternate sections were stained with hæmatoxylin and eosin.

Activity of monoamine oxidase was indicated by formazan deposits, 'Nitro-*BT*' yielding blue and '*TNBT*' brownish granules. In the uninjured skin farther away from the wound the basal and spinous layers of the epidermis, and the outer root sheaths of the hair follicles showed intense enzyme activity. The most striking colouring was demonstrated in the sebaceous glands. The dermal fibroblasts exhibited only a faint monoamine oxidase reaction.

The first increase in monoamine oxidase activity could be seen in the wound periphery 1 h after the injury. The increase became more distinct after 2 h (Fig. 1). Monoamine oxidase active dermal fibroblasts could be demon-

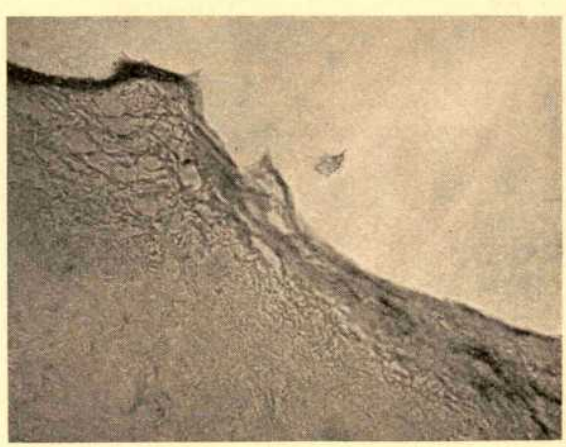

Fig. 1. Photomicrograph (× *c.* 83) of a 2-h injury. Monoamine oxidase activity appears peripherally to the edge of the wound. (Method of Glenner[4], by using 'Nitro-*BT*').

strated in a peripheral area, 200–500μ beyond the edge of the wound, whereas in the immediate vicinity of the edge the activity began decreasing. In a 4-h wound, the monoamine oxidase pattern resembled that observed after 2 h, the descent in the nearest surroundings of the injury being, however, more pronounced. In an 8-h wound, the activity had already diminished even in the peripheral fibroblasts. After 16 h, no increased activity of monoamine oxidase could be demonstrated in the wound periphery. Four hours after the injury, leucocytes began to invade the peripheral area, but no distinct leucocytic zone could be seen until 8 h had elapsed. Afterwards, the peripheral zone with increased cellularity took up a non-specific weak staining which resisted the pre-incubation inhibition. By contrast, both the increased monoamine oxidase activity demonstrable in 1-, 2-, 4-, and 8-h wounds, and the activity of the uninjured skin disappeared in the control sections, pretreated in the inhibitor solution. The enzymatic pattern observed by using 'Nitro-*BT*' was similar to that of '*TNBT*'. The latter tetrazolium salt, however, appeared to be more effective in detecting a relatively faint activity, for example, that observed in a 1-h wound.

In conformity with other enzyme reactions in wounds[6] the continuous decrease in monoamine oxidase activity in the nearest surroundings of the injury should be considered as an early sign of imminent necrosis. Even here, the hair follicles seem to be more resistant than the dermal elements.

In the wound periphery monoamine oxidase activity was increased from one to eight hours after the injury, disappearing thereafter. During the very first phase monoamine oxidase may, thus, contribute to the inflammatory vasodilatation which subsequently seems to be maintained by other factors.

One to eight hours post-operatively an initial increase in the activity of several hydrolytic and oxidative enzymes[6–9] and of transglucosylases[10] has been observed in the peripheral area of healing wounds. A defensive role, for example, in connexion with phagocytosis, has been ascribed to many of these enzymes[6–9]. The injury affecting the connective tissue cells in the peripheral wound zone seems, thus, to serve as a stimulus, activating local defence forces after a short mobilization time. Monoamine oxidase apparently joins these defence mechanisms by contributing to the initial vasodilatation, that is, the vascular response to injury.

Carbonic Anhydrase and Formation of the Hen's Egg Shell

Mainly because of the observed inhibitory effects of sulphonamides on egg shell formation[1–3] and partly because the enzyme carbonic anhydrase is present in the reproductive tract of the laying hen[4], it has been generally assumed that this enzyme plays an important part in egg-shell formation by making available the carbonate ion. Nevertheless, while some workers[4,5] have attempted to correlate egg-shell formation with increased carbonic anhydrase activity of the uterine tissue of laying hens, little attention has been focused on the role the shell membrane might play during shell deposition. The keratin-like shell membranes[6] which enclose the egg-white are believed to be attached to the major part of the shell by a mammillary layer, so called because of the presence of numerous aggregates (the mammillæ) of a substance with the staining characteristics of a mucoprotein[7].

This preliminary report of work using histological staining techniques indicates that the mammillary layer can be considered both as a special layer of the outer shell membrane and as an initiator of shell deposition. Mammillary layer preparations were made by decalcifying pieces of shell for 60 min (or whole shell eggs for 24 h) in aqueous solutions of ethylenediamine tetraacetic acid (5 per cent w/v) adjusted to *p*H 8·5 with a 10 N sodium hydroxide solution. To aid microscopic observations the mammillæ and membranes were stained with aqueous alcian blue (1 per cent w/v) and acid fuchsin ($\frac{1}{2}$ per cent w/v) solutions respectively.

Fig. 1 is a surface view of the outer shell membrane obtained by decalcifying the shell of a whole egg. The inner shell membrane was discarded and the four layers of the outer shell membrane were exposed by tearing away an edge of the membrane with a pair of forceps. The outermost layer of the membrane to which the mammillæ are attached (Fig. 2) represents a part of the outer shell membrane additional to the three layers described by Moran and Hale[8]. Treatment for 1 h at 32° C of fresh unfixed samples of the mammillary layer with a solution containing cobalt sulphate and sodium bicarbonate according to Hausler's[9] modification of Kurata's[10] method (see ref. 11) has shown that the enzymatic activity of carbonic anhydrase is concentrated at the mammillæ.

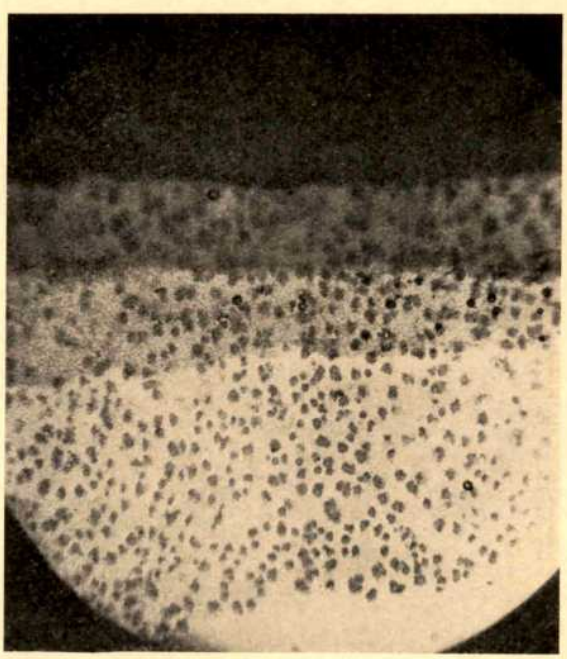

Fig. 1. Surface view of the outer shell membrane showing four layers. The mammillæ appear as dark spots on the outermost layer of the membrane. (× *c.* 30)

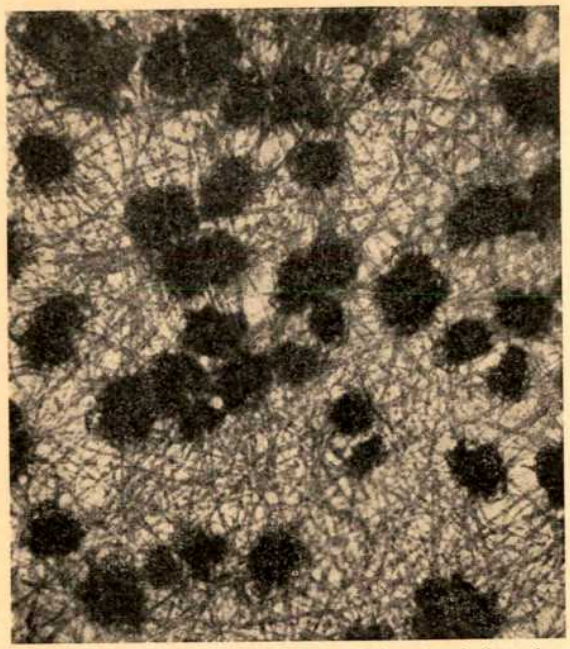

Fig. 2. Surface view of the outermost layer of the outer shell membrane showing the distribution of the mammillæ. (× *c.* 240)

Failure of membranes to retain cobalt either after boiling for 15 min or in the absence of bicarbonate ions and the observed inhibition of the staining reaction by 4×10^{-2} M 'Diamox' (2-acetylamino-1,3,4-thiadiazole-5-sulphonamide sodium) confirms the presence of carbonic anhydrase.

Studies with shell-less eggs removed from the uteri of laying hens confirm the presence of the fourth layer of the outer shell membrane before deposition of the shell, and the presence of carbonic anhydrase at the sites of the mammillæ. The enzymatic activity in the membranes of eggs removed from the uterus seems to be greater than that observed with membranes isolated from complete egg shells and in the former case an incubation period of 15 min was sufficient to demonstrate the enzymatic activity.

Although the overall mechanism of shell formation involving the transfer of calcium ion from the uterine fluid to egg shell is unknown, it seems likely that carbonic anhydrase situated at the mammillæ aids shell deposition by catalysing the decomposition of H_2CO_3, a component in the equilibrium reaction $2HCO_3^- \rightleftharpoons H_2CO_3 + CO_3^=$, and thus increases the amount of available carbonate ion at the sites of calcification. It is assumed that bicarbonate ions are readily supplied by the blood stream of the laying hen during shell formation.

We thank Cyanamid of Great Britain for a gift of 'Diamox' (sodium salt).

Note added in proof. Terepka[12], from studies with polarized light, has proposed that the shell consists of structural units extending radially from the mammillary projections. The identification of carbonic anhydrase activity at the mammillæ affords a possible mechanism for the initiation of such a development.

PATHOLOGY

Experimental Production by 2-ethyl-2-phenyl Butyramide of Intrahepatic Cholestasis with Bile Plugs in Dogs

Oral administration of 2-ethyl-2-phenyl butyramide in dogs produces intrahepatic cholestasis with bile plugs in bile canaliculi. Intrahepatic cholestasis with bile plugs is observed in a small percentage of patients receiving chlorpromazine, C-17 alkylated steroids, or several other chemically unrelated drugs. Histologically[1], this condition is characterized by bile plugs in bile canaliculi and deposition of bile pigment in liver and Kupffer cells. Changes in hepatic parenchymal cells, usually in the form of feathery degeneration and more rarely in the form of focal necrosis, are regarded as secondary to the biliary stasis. Infiltration of portal tracts was reported occasionally. Electron microscopic examination[2] of these livers showed dilation of some bile canaliculi and alteration in the microvilli of practically all; the microvilli were either absent or stunted and irregular in shape. Although functional[3] as well as histochemical and ultrastructural[4] changes were demonstrated in the livers of rats dosed with C-17 alkylated steroids, typical intrahepatic cholestasis with bile plugs has not been produced by a drug in normal animals[1].

The compound 2-ethyl-2-phenyl butyramide—$C_3H_5(C_6H_5)(C_2H_5)CONH_2$ was described in 1926[5] as a hypnotic with severe hepatic toxicity, but no histological data were reported at that time.

Dogs receiving 50 mg/kg/day of this compound for 4 days showed in hæmatoxylin–eosin stained paraffin sections typical bile plugs in bile canaliculi without significant changes in hepatic parenchymal cells or infiltration of portal tracts. The combined *BSP–PSP* liver and kidney test showed significant *BSP* retention and normal *PSP* elimination[6].

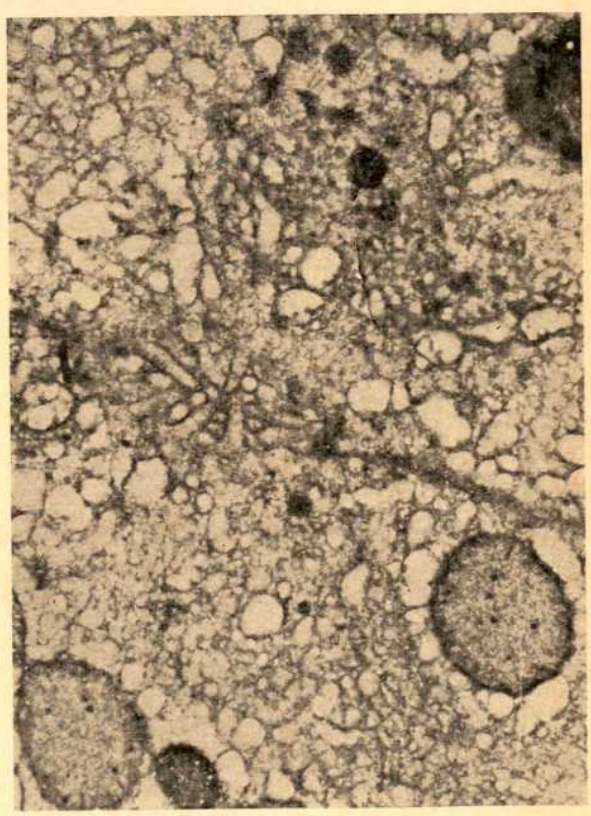

Fig. 1. Electron photomicrograph of liver from dog dosed orally for 4 days with 50 mg/kg/day 2-ethyl-2-phenyl butyramide. Canaliculus with distended interlacing microvilli is shown in the centre. Above and to the left of the canaliculus electron dense material is present in the Golgi vesicles. Uranyl acetate stained section. (× 18,600)

Fig. 2. Electron photomicrograph of same case as Fig. 1. Canaliculus distended with bile plug. (× 8,800)

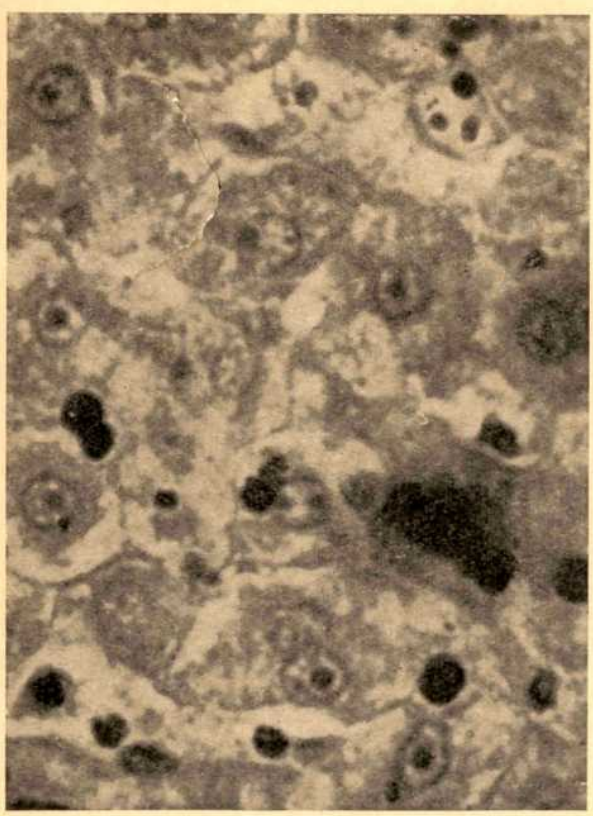

Fig. 3. Hæmatoxylin and eosin stained liver section from dog dosed orally for 11 days with 50 mg/kg/day 2-ethyl-2-phenyl butyramide. Bile plugs in canaliculi and degenerative changes in liver cells

The electron microscope revealed some canaliculi filled with dense material which obscured the microvilli; these corresponded to the bile plugs seen in light microscopic sections. More commonly we found canaliculi with long slightly distended interlacing microvilli and indistinct lumina with little or no bile. Adjacent to many of these altered canaliculi electron-dense material occupied the vesicles associated with the Golgi apparatus (Fig. 1). In other instances a canaliculus filled with bile was seen which appeared ready to burst into an adjacent space between two hepatic cells (Fig. 2). In this space microvilli appeared relatively normal.

The administration of the same dose for 11 days showed in hæmatoxylin–eosin stained paraffin sections severe intrahepatic cholestasis with feathery degeneration, single cell necrosis, and acidophilic bodies (Fig. 3).

Red blood cell survival times studied with Squibb 'Chromitope Sodium' in control dogs and in dogs dosed with 2-ethyl-2-phenyl butyramide showed no significant differences between test and control animals; this means hæmolysis had not occurred.

The availability of a simple chemical substance which will produce within a very short time intrahepatic cholestasis in dogs appears to be a worthwhile tool for the investigation of the mechanism of bile secretion and the pathogenesis of intrahepatic cholestasis. We are at present investigating the effect of 2-ethyl-2-phenyl butyramide on the morphology and histochemical reactions of the rat liver.

Homograft Antigens: Isolation of Fractions of Normal Cells which retain Activity after Freeze-drying

In previous reports[1], we have described the isolation from splenic and lymph node cells of homograft antigens which required immediate bioassay, because they lost antigenic activity rapidly on standing and were almost totally inactivated by simple freezing or by freeze-drying. These early preparations, however, afforded materials which enabled us to develop an assay procedure and to examine some of the properties of antigenic fractions. In the course of these examinations, newer methods of antigen preparation were devised, based on the isolation of subcellular fractions from sucrose solutions. Brent *et al.*[2], Manson *et al.*[3] and Davies[4] have recently reported the preparation of transplant antigens from sources and by methods that differ from those described below.

Mice were obtained from the Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine, with either *A/Jax*, *C3H*, *C57BL6*, or *Balb/c* used as the donor strains, and male *C57BL6* or male *A/Jax* as the recipient strain. Antigens were prepared from the tissue of either all male or mixed male–female populations. All animals were allowed to reach 20 g in weight before use.

As the source of antigenic materials, we used 30–50 spleens or pooled sets of lymph nodes (cervical, axillary, infrascapular, mesenteric, and inguinal) or 70–80 thymus glands. Organs were collected and rinsed in cold buffered sodium chloride solution (0·13 M sodium chloride, 0·01 M

phosphate, *p*H 7·2–7·4) followed by rinsing with solution *A* (0·25 M sucrose, 0·03 M ethylenediamine tetraacetic acid adjusted to *p*H 7·2–7·4 with potassium hydroxide, sp.g. about 1·03). 5–8 spleens were sliced longitudinally on a 4–5-in. square of 40-mesh stainless steel screen and were pressed through it with the end of a flexible spatula blade. Lymph nodes and thymus glands were cut coarsely with a small scissors and fragmented directly in a homogenizer. Spleens were kept wet with solution *A* and eventually washed into the plunger-type homogenizer previously described[5], with short intense bursts of the same solution *A* delivered from a polyethylene wash bottle. A final volume of 3–4 ml. per spleen or set of lymph nodes has proved convenient but not critical. The cellular material was then comminuted in the homogenizer with a 'loose' plunger (10–12 complete cycles), and the resulting homogenate was placed in 250 ml. polypropylene bottles and sedimented twice for 15 min at about 1,550*g* (max.) in order to remove nuclear debris, whole cells, etc. The sediments were combined and reserved for a 'chemical cell-count' by DNA estimation, since solution *A* causes irreversible aggregation of cells and makes a direct count in a hæmocytometer impossible.

The cloudy supernatant suspension was skimmed as free of floating fat as possible and sedimented for 1 h at 30,000 r.p.m. in the No. 30 rotor of a model L Spinco preparative ultracentrifuge (105,000*g* max.). The supernate, I, was decanted from the sediment, II, and the sedimented pellets were gently rinsed with 0·25 M sucrose.

Sediment II was further fractionated by centrifugation at successively greater speeds in solution *B*, 0·25 M sucrose, 0·002 M ethylenediamine tetraacetic acid (adjusted to *p*H 7·5–7·6 with potassium hydroxide). Volumes of 0·75–0·9 ml. per spleen or set of lymph nodes have proved convenient.

The suspension in solution *B* was sedimented in the following sequence of rotational speeds in the indicated head or rotor of the Spinco preparative ultracentrifuge (model *L*), the sedimented materials being collected at each speed: (*a*) 5,000 r.p.m. for 60 min in head *SW* 25 (4,000*g* max.); (*b*) 8,000 r.p.m. for 60 min in the same head (8,000*g* max.); (*c*) 20,000 r.p.m. for 120 min in rotor number 30 (60,000*g* max.), and (*d*) 40,000 r.p.m. for 60 min in rotor number 40 (140,000*g* max.). By means of this scheme the following fractions were isolated in solution *B*: (*a*) a dark gelatinous pellet, III; (*b*) a gelatinous pellet, somewhat turbid in appearance, IV; (*c*) a large gelatinous pellet, shaded yellow, V; (*d*) another gelatinous pellet, VI. For the sedimentations at 5,000 and 8,000 r.p.m., a Spinco *SW* 25 (swing) head was required in order to recover the poorly packed layers. At the higher speeds Spinco No. 30 or 40 rotors (angle head) were satisfactory.

All sediments were resuspended in 0·002 M ethylenediamine tetraacetic acid (*p*H 7·2–7·4) and were centrifuged for about 5 min at 250*g* to sediment adventitious material. Aliquots were then removed for biological assay, chemical assay, and freeze-drying. The aliquots for bioassay were brought to their final volumes with buffered 0·13 M sodium chloride, so that the desired dose was contained in a volume of 2 ml. The results of a typical bioassay[5] are outlined in Table 1. (In the scoring system in Tables 1 and 2, the integers 0–6 correspond to 0, 10, 25, 50, 75, 90 and 100 per cent survival of epithelium. Zero, therefore, represents maximal measurable antigenicity.)

Table 1. Fractionation of Lymph Node Cells and a Comparison of their Activities. Experiment 63-17 (*Balb/c* to *C57BL6*)

Fraction No.	Score (Averages of scores of 6 or 7 animals)	Dose per animal mg (dry weight)	Recovered total dry weight (mg per donor animal)
III	0·6	2·2	2·3
IV	0·1	0·8	0·7
V	1·1	1·0	1·0
VI	2·8	0·3	0·15

As can be seen in Table 1, all fractions show considerable activity, but our results have shown the consistent pattern of appearance of the greatest activity in fractions IV and V. These correspond to fractions containing membranes of the cytoplasm and cell surface. The use of ethylenediamine tetraacetic acid probably causes the complete disassociation of microsomal RNA–protein–lipoprotein complexes, so that the morphological features of the active fractions would be obscured by this treatment.

Preliminary efforts at sucrose gradient sub-fractionation of sediment II have afforded several active sub-fractions. One fraction was recovered between sp.g. 1·17 and 1·18, and a second between sp.g. 1·125 and 1·150 (appropriate layered sucrose concentrations, 0·002 M in ethylenediamine tetraacetic acid brought to *p*H 7·3–7·5 with potassium hydroxide). Separation was accomplished in an *SW* 25 head of a Spinco model *L*, 25,000 r.p.m. for 120 min. These observations are now being extended.

All the fractions described here can be freeze-dried in 0·002 M ethylenediamine tetraacetic acid solution (*p*H 7·2–7·3) with retention of a high degree of antigenic activity when re-assayed as long as 25 weeks after preparation. Activity is also well preserved after storage overnight at 3° C in the same solution. Typical data are shown in Table 2. Freeze-drying was carried out in an apparatus of our own design, under pressure of 0·03–0·05 mm mercury. Drying was completed in 2–3 h, and all samples were collected under pre-purified (water-pumped) nitrogen and stored in the freezing compartment of an ordinary refrigerator (−5° to −12° C).

Table 2. Comparison of Freshly Prepared Antigen with Freeze-Dried Material

	Age of Antigen	Dose in dry wt. (μg)*	Recipient strain	Score (Averages of groups of 6 or 7 animals)
Exps. 62-13 (*C57BL6* Spleen) Fracts. IV and V (0·57 mg recovered per donor animal)*	Fresh	200	*A/Jax*	0·3
	Freeze-dried (8 wk.)	350	*A/Jax*	0·9
	Freeze-dried (25 wk.)	200	*A/Jax*	0·2
Exps. 63-3. (*C57BL6* lymph node and spleen) Fract. V (0·70 mg recovered per donor animal)*	Fresh (not tested)			
	Freeze-dried (3 days)	1,080	*A/Jax*	0·1
	Freeze-dried (22 days)	490	*C3H*	0·9, 1·0
	Freeze-dried (23 days)	110	*C3H*	1·0
		110	*A/Jax*	1·0
		110	*Balb/c*	0·3

* Not corrected for inclusion of EDTA.

Although we have prepared antigenic fractions from pre-frozen tissue, the activities of these fractions have not been as high, on a per organ basis, as material prepared from fresh organs.

Analyses, carried out in attempts to define even broadly the classes of materials present in the various sub-fractions, have indicated only that the active material is essentially lipoprotein. When applied to this material, procedures which are known to denature lipoproteins cause the loss of antigenic activity (deoxycholate, 'Triton *X*-100', organic solvents, etc.). The difficulties presented by the contamination of micro-samples with relatively large amounts of absorbed ethylenediamine tetraacetic acid and sucrose have been solved in part by dialysis. In general, the antigenic materials have shown the following ranges of composition: lipid, 30–60 per cent (lipid sterol as cholesterol, 40–70 per cent of lipid); protein, 20–40 per cent; DNA, less than 0·1 per cent (when detected by colorimetric determination with indole[6,7]); RNA less than 5 per cent (as determined by ultra-violet absorbance at 260 mμ of the appropriate Schmidt–Thannhauser fraction[7]).

While 0·25 M sucrose is a customarily used concentration[8], we found that it was necessary to use an ethylenediamine tetraacetic acid concentration of 0·03 M in order to suppress the tendency of DNA to disperse in solutions

of low ionic strength. This has not been completely successful since the amounts of DNA appearing in the supernatant of sediment I have been found to be about 5 per cent of the total DNA recovered in the typical preparation. Similar observations have been reported, for example, in the fractionation of ascites tumour cells[9]. Although DNA-histone is found to be less than 0·1 per cent in our most active preparations, we cannot yet rule out the nucleus as the source of some antigenic material.

The material described by Davies[4] which is isolated from ascites tumour fluid is a lipoprotein that is active in the hæmagglutination inhibition system of Gorer. More recently, Manson *et al.*[3] have reported on a material isolated from a strain-specific mouse spleen cell and lymphosarcoma, grown in cell culture, which also appears to be a lipoprotein. It is reported to be active in a transplant system, but differences in the assay system that they have used and our assay system preclude a comparison of the two preparations.

'Refuin': a Non-cytotoxic Carcinostatic Compound proliferated by a Thermophilic Actinomycete

'Refuin' is a high-molecular fraction of a fermentation beer produced by a thermophilic actinomycete. The fraction is recovered by precipitation with ammonium sulphate and by fractional ice crystallization. Although the fermentation temperature is 50° C, the active principle is heat-labile, losing all activity after 6 h at room temperature. Electrophoretic analysis reveals a ninhydrin staining positively charged band.

The morphology and general physiology of the *Thermoactinomyces* sp. producing 'Refuin' was determined by methods previously described[1].

'Refuin' was evaluated for antibiotic activity, *KB*-cell line tissue culture toxicity, and for carcinocidal or carcinostatic activity on four mouse tumour systems: sarcoma 180, carcinoma 755, leukæmia 1210, and Ehrlich ascites.

Activity against Gram-negative organisms was not noted. The Gram-positive activity was highly specific. Although *B. subtilis* was not inhibited and *S. aureus* 209 *P* was only slightly inhibited, *Mycobacterum smegmatis*, *Torulopsis albida* and *S. aureus* respiratory deficient mutant culture *AT CC UV* 2–13680 were strongly inhibited.

The anti-tumour activity in the sarcoma 180, adenocarcinoma 755, and leukæmia 1210 was conducted according to the National Institutes of Health protocols 1 : 301–302 of June 1962. A daily intraperitoneal injection of 50 mg/K of 'Refuin' causes a 75 per cent inhibition of the sarcoma 180 tumour and a 60 per cent inhibition of the adenocarcinoma 755 tumour. No leukæmia 1210 activity was observed.

The Ehrlich ascites assay results are summarized in Table 1. 10^6 ascites cells were inoculated intraperitoneally and immediately followed by a subcutaneous injection of 50 mg/K of 'Refuin'. Although the subcutaneous route is not reported to be effective for administration of other anti-tumour agents, 'Refuin' showed significant activity when administered either subcutaneously or intraperitoneally. Although the intraperitoneal route gives better results, the subcutaneous route permits more critical evaluation of our system. Of special interest was the effect of 'Refuin' in converting the fluid ascitic cells to a small solid tumour in 45 per cent of the treated mice. Upon continued administration of 'Refuin', necrosis and ultimate disappearance of this tumour resulted in many of these mice.

Table 1. Activity of 'Refuin' on Ehrlich Ascites Mouse Tumour System when Administered Subcutaneously

	Treated group	Control group
Number of mice	100	47
Number of mice showing conversion of ascites to solid tumours	45	0
Average survival of those mice showing progressive development of ascites	19·9 days	9·8 days
Number of mice showing total disappearance of ascites and tumour	18	0

Mortalities or excessive loss of weight due to administration of 'Refuin' were not noted. A LD_{50} on unimplanted mice was not obtained since the maximum dose that could be conveniently administered intravenously (700 mg/K) proved non-lethal.

In the *KB* cell line tissue culture system 'Refuin' caused negligible inhibition. This would suggest that the oncostatic activity of 'Refuin' is dependent on the host defences. This lack of tissue culture activity, the lack of systemic toxicity, and its very limited antibiotic spectrum differentiates 'Refuin' from the other anti-tumour agents known at present.

All drugs other than hormones and steroid that are of value in cancer therapy have shown considerable toxicity. As stated by Moore[2] toxicity is a prerequisite for anticancer activity. Indeed, since the drugs presently used for the palliation of neoplastic disease exert their greatest effect on rapidly dividing cells, they also induce toxic symptoms in bone marrow, gastrointestinal mucosa, skin, liver, and lymph nodes. The clinical evaluation of 'Refuin' now in progress has confirmed the lack of systemic toxicity of this drug and gives promise of confirmatory clinical evidence of anti-tumour activity.

IMMUNOLOGY

Preparation of an Antiserum Specific to a Spontaneous Mouse Leukæmia after the Induction of Artificial Immunological Tolerance to Normal Mouse Tissue

The feasibility of preparing antiserum to the transplantable Ehrlich ascites tumour after the induction of immunological tolerance to normal mouse tissue antigens in the neonatal rabbit has been reported previously from this laboratory[1,2]. Such tolerant anti-Ehrlich ascites tumour sera, when tested *in vivo*, were toxic for the tumour and relatively innocuous for the murine host.

Non-tolerant anti-Ehrlich ascites tumour sera displayed far greater murine toxicity, and no greater, or decreased, protection against the transplanted tumour. Antisera to normal tissues from animals previously made tolerant to the same tissues have no increased anti-tumour effect, and non-tolerant anti-normal tissue sera have not only no increased anti-tumour activity, but are highly murine toxic. Other authors, using *in vitro* tests, have reported similar findings on other tumours[3,4].

Since the Ehrlich ascites tumour is not spontaneous in the strain of mice used (*C3H*), the specificity reported cannot unequivocally be attributed to antibodies directed against antigenicities unique to the malignancy, but may represent antibodies to antigenicities of the original strain in which the tumour arose which are not represented in *C3H* mice. In order to see if protective specificity to a spontaneous tumour could be demonstrated after the induction of artificial immunological tolerance toward normal tissue antigens, experiments were begun using isogenic *AKR/Jax* mice and the lymphatic leukæmia which arises spontaneously in this strain. The preliminary experiment using this system is reported here.

By a method similar to that used with the Ehrlich ascites tumour system[1,2], immunological tolerance toward a homogenate (consisting mostly of whole cells) of normal *AKR/Jax* mouse spleens, thymuses, livers, lungs, and peripheral and mesenteric lymph nodes was induced in neonatal Dutch rabbits. The first injection, containing 50 mg of tissue (wet weight), was given within 12 h after birth. Ten more daily injections of the same amount of tissue were given followed by another ten injections each containing 100 mg (wet weight) of tissue. During the 10th post-natal week, these rabbits were divided into two groups. One group received 1·25 g (wet weight) of a similar tissue homogenate from leukæmic mice, given in four injections every other day (tolerant anti-leukæmia serum). The second group received the same amount of tissue according to the same injection schedule from normal mice (tolerant anti-normal tissue serum). Litter-mates uninjected at birth received like injections of one of the homogenates from either leukæmic or normal mice (non-tolerant anti-leukæmia serum, and non-tolerant anti-normal tissue serum). All rabbits were bled for antiserum 14 days after the last immunizing injection.

The spleens, and peripheral and mesenteric lymph nodes from leukæmic *AKR/Jax* mice were obtained and minced and the single cells were collected in 0·9 per cent sodium chloride; 7×10^7 cells were injected subcutaneously into normal *AKR/Jax* mice. A total of 1·2 c.c. of one of the antisera or normal rabbit serum was injected by the intraperitoneal route into these animals: 0·4 c.c. within 2 h after tumour administration, and 0·4 c.c. on each of the two subsequent days. The survival of mice in each of the groups is given in Table 1.

Table 1. Effects of 1·2 c.c. of tolerant and non-tolerant anti-*AKR* leukæmia and tolerant and non-tolerant anti-*AKR* normal tissue sera on the survival of *AKR* mice inoculated with 7×10^7 leukæmic cells

Antiserum given	No. of mice per group	Mean survival (days)	Last day of survival of any group member
Tolerant anti-leukæmia	6	22·2	27
Non-tolerant anti-leukæmia	6	16·7	25
Tolerant anti-normal tissue	3	16·7	19
Non-tolerant anti-normal tissue	4	17·8	19
Normal rabbit serum	4	15·5	18

It can be seen that the tolerant anti-leukæmia serum conferred a survival advantage on mice so treated that was not seen in any other group. The mean survival for this group was 22·2 days, and the last surviving mice were also in this group. Tolerant and non-tolerant anti-normal tissue serum survival levels did not appreciably differ from those seen for normal rabbit serum. The mean survival of mice receiving non-tolerant anti-leukæmia serum was of the same order, although one mouse did survive almost as long as some members of the tolerant anti-leukæmia group.

It should be noted that mice receiving the non-tolerant anti-leukæmic or anti-normal *AKR* sera did not regularly display the immediate murine toxicity seen when comparable amounts of non-tolerant anti-Ehrlich ascites tumour serum or non-tolerant anti-*C3H* normal tissue serum were administered to *C3H* mice in previous experiments with this system[1,2]. Only one mouse given non-tolerant anti-leukæmia serum succumbed from the immediate effects of the antiserum. This may be due to toxic characteristics of antisera against the *AKR* normal tissue or leukæmia, different from those against the *C3H*-Ehrlich ascites tumour system. However, the more probable explanation is that the anti-*AKR* sera were generally weaker, resulting from the circumstances that the rabbits were immunized with four rather than the usual six injections. This situation occurred because of a lack of available injection antigen.

It thus appears that while tolerance to normal tissues is induced in neonatal rabbits by the injection of normal antigens of an isogenic strain of mice, this does not prevent the formation of antibodies, on subsequent immunization with a leukæmia arising spontaneously in this strain. It is probable that some or all of these antibodies are specific for antigens found uniquely in the malignant state.

Persistence of Antigen in Nucleoprotein Fractions of Mouse Spleen Cells during Antibody Formation

The fate and distribution of antigenic determinants in immunized animals is largely unknown[1]. There has been much speculation and experimentation concerning persistence of antigen during the period of antibody formation, as well as possible relationship of persisting antigen to specific immunological tolerance[2,3]. Recent work has indicated that neonatal injections of soluble antigens derived from *Shigella* micro-organisms may result in specific immune unresponsiveness in young mice[4,5]. It was postulated that 'excess' antigen, analogous to pneumococcal polysaccharide, may persist for extended periods of time in the mouse tissues, and thus induce an unresponsiveness similar to 'immunological paralysis'[6].

In an attempt to learn more about the normal fate and biological activity of *Shigella* antigens injected into mice, an investigation was designed to test for possible persistence of antigen in mouse spleens at various periods following immunization. For this purpose *NIH* white mice, 6–12 weeks of age, were injected intravenously with 0·1–0·5 ml. soluble antigenic material (20 μg N) derived from *Shigella paradysenteriae* by partial trypsin digestion of a 10 per cent suspension of alcohol-killed *Shigella*[4,7]. Serum samples were obtained by retro-orbital puncture from each mouse at various times following injection to ascertain agglutinin response[4]. Groups of such immunized mice were killed at 1 day, 1, 2 and 3 weeks following injection and spleen cell suspensions prepared in Hanks's balanced salts solution. Cell-free homogenates were prepared using 'Teflon'-tipped tissue homogenizers at 4° C. Nuclei and mitochondria containing fractions were obtained by differential centrifugation, while ribonucleoprotein (RNP) and deoxyribonucleoprotein (DNP) rich fractions were obtained by salt extraction procedures[8,9].

No detectable *Shigella* antigen or anti-*Shigella* antibody could be observed in any of the fractions, except in those

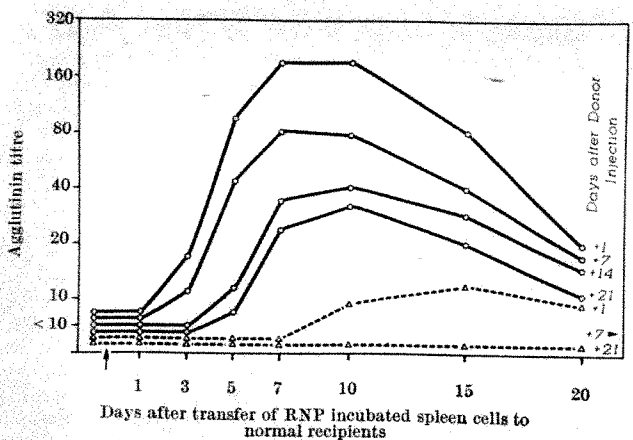

Fig. 1. Agglutinin formation in normal, non-immunized recipient mice receiving normal mouse spleen cells which had been incubated with spleen ribonucleoprotein fractions (RNP) derived from *Shigella* immunized donor mice. Each curve represents mean titre of at least six recipients. 0·4–0·9 mg N of immune spleen RNP incubated for 1 h with 2–9 × 10^7 normal spleen cells, either untreated (0) or heated for 30 min at 56° C (△) prior to incubation. RNP prepared by salt extraction method (ref. 9) 1, 7, 14 and 21 days after intravenous injection of donor mice with 0·5 ml. soluble *Shigella* antigen (20 μg N)

obtained one day following injection, by means of complement fixation, tanned cell hæmagglutination, precipitin, and agglutination tests. Injection of these fractions into non-immune recipient mice failed to elicit a marked anti-*Shigella* response. In order to test further for possible presence of *Shigella* antigenic material in the sub-cellular spleen fractions 1·0-ml. samples (0·4–0·9 mg N) were incubated for 1 h with 1·0 ml. sterile Hanks's solution containing 30 per cent normal rabbit serum and 2–9 × 10^7 normal spleen cells obtained from another group of non-immunized *NIH* mice, 6 to 10 weeks of age. Following incubation, each cell suspension mixture was carefully washed three times with sterile Hanks's solution by serial centrifugation and injected intravenously into a fresh group of non-immunized *NIH* recipient mice, 6–10 weeks of age. One mouse was used as a recipient for each incubation mixture. At least six spleen cell suspensions were incubated for each original spleen cell fraction. Controls consisted of: (1) similar incubation mixtures containing cell suspensions previously heated at 56° C for 1 h prior to incubation; (2) cell suspensions incubated with saline instead of spleen cell fractions; (3) cell suspensions incubated with cell fractions obtained from control, non-immunized donor mice.

Serum samples were obtained from each recipient mouse at 1, 3, 5, 7, 10, 15 and 20 days following transfer and tested for anti-*Shigella* agglutinins. Nearly all the mice receiving normal, unheated spleen cell suspensions incubated with the immune spleen sub-cellular fractions responded with readily detectable agglutinin formation within 3 to 5 days following cell transfer (Table 1). Very few recipients receiving control-heated spleen cells incubated with donor spleen cell fractions responded with any agglutinins. Those that did had lower titres and a marked delay in the appearance of agglutinins. No recipient receiving normal spleen cell suspensions incubated with saline only, or incubated with fractions from normal control donors, revealed any agglutinin formation above the threshold level of measurement. Other experiments failed to reveal a similar agglutinogenic effect with sub-cellular fractions from liver or lung tissues from similar immunized donor mice.

Table 1. AGGLUTININ FORMATION IN NON-IMMUNIZED MICE RECEIVING NORMAL SPLEEN CELL SUSPENSIONS INCUBATED *in vitro* WITH SPLEEN CELL FRACTIONS FROM *Shigella* IMMUNIZED DONOR MICE*

Immune spleen cell fraction†	Day following *Shigella* injection‡ 1	7	14	21
RNP	196 (11/14)§	68 (10/12)	49 (7/11)	47 (8/10)
DNP	48 (8/15)	31 (6/10)	21 (3/8)	8 (0/10)
Mitochondria	75 (7/11)	32 (4/8)	30 (3/7)	15 (1/6)
Nuclei	69 (8/10)	48 (4/9)	10 (1/8)	8 (0/8)
Whole homogenate	132 (10/11)	62 (7/11)	40 (2/6)	28 (3/8)

* 2–9 × 10^7 normal, washed spleen cells incubated with 0·4–0·9 mg immune spleen cell fractions.
† Prepared from immune whole cell suspensions by differential centrifugation and salt extraction procedures (refs. 8 and 9). Negative results obtained with similar fractions from non-immunized donors.
‡ Original donor mice injected intravenously with 0·5 ml. soluble *Shigella* antigen (20 μg N).
§ Mean peak agglutinin titres of recipient mice. No. of recipients with peak titres 1 : 20 or greater per number receiving incubated spleen cells.

The rapid appearance of agglutinins in normal mice receiving the fresh normal spleen cells incubated with sub-cellular fractions from immunized donors suggested that immunogenic quantities of *Shigella* antigens were present in the original fractions and could stimulate an agglutinin response by the incubated spleen cell suspensions. The major immunogenic activity of the donor spleen cells appeared to be associated with ribonucleoprotein-rich fractions (Table 1 and Fig. 1), although all the fractions from immune donors incubated with normal spleen cells stimulated some degree of agglutinin response. RNP fractions obtained from donors 3 weeks after immunization, when agglutinin responses were diminishing, still revealed agglutinogenic activity (Fig. 1), while the other fractions, including homogenates, nuclei, mitochondria and DNP-rich material, had either low or no immunogenic activity at the second or third week following immunization.

The results presented are in agreement with suggestions by others that immunogenic activity of antigenic determinants may persist for some time in tissues of immunized animals[10,11]. However, the possibility of the transfer of *de novo* antibody-forming capacity by means of immune spleen cell nucleoproteins or sub-cellular fractions, as suggested previously[12,13], has not been eliminated by these experiments.

RADIOBIOLOGY

A Rapid Method for Estimation of Iodine-131 in Milk

Cosslett and Watts[1] have described a method for the removal of iodine-131 from milk by means of an anion exchange resin prepared in the chloride form. They reported 96–98 per cent retention of radioactive iodine by the resin and assumed that the iodine residual in the milk was present as a non-ionic species. Lengemann and Swanson[2], Garner[3] and Morgan[4] have all found non-ionic iodine (that is, protein-bound) in cow's milk, whereas Glascock[5], Wright, Christian and Andrews[6] believed that all physiologically occurring iodine-131 was completely ionized.

Morgan[4] concluded that resin treatment of cow's milk was of value only in removing ionic iodine. In order to clarify this point, the following experiment was performed. A 5-l. pooled sample of milk, representing a collection from about 300 cows, was subjected to ultrafiltration. At

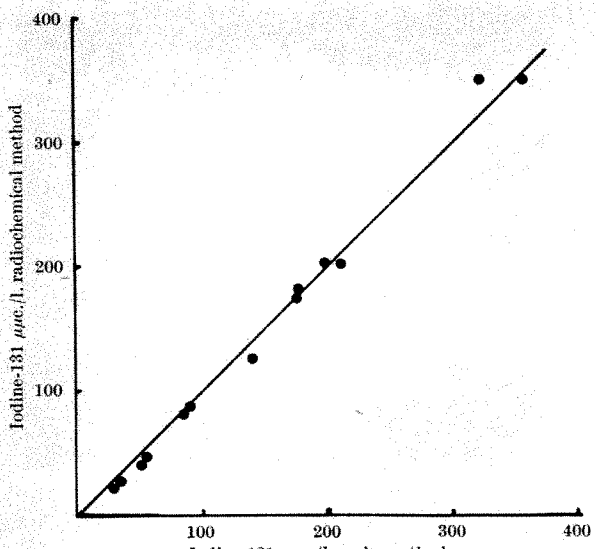

Fig. 1. Comparison of methods

this time the iodine-131 concentration in milk was about 100 μμc./l. as a result of fall-out from weapon testing. Radiochemical analysis of the ultrafiltrate and residue indicated that 60 per cent of the iodine-131 was present in the ultrafiltrate. Samples of the original milk were then passed through an anion exchange resin column. Duplicate analysis showed 100 per cent retention of iodine-131 by the resin. From this we concluded that radioactive iodine complexed with protein was quantitatively removable by resin treatment.

Details of our experimental technique for the estimation of iodine-131 in milk are:

50 ml. of wet 'Deacidite *FF*', 3–5 per cent cross-linking (*SRA* 63) 14–52 mesh in the chloride form, are transferred to a column of dimensions 25 cm × 1·5 cm. One litre of fresh milk is then passed through the column at a flow-rate of 5 ml./min. On completion the resin is blown out of the column into a clean beaker using compressed air, washed twice by decantation with 100 ml. demineralized water and transferred to a polystyrene container (6·5 cm diam. × 2 cm high) which fits on top of a sodium iodide crystal. We have shown that this washing procedure causes no loss of activity. Indeed, the resin can be acetone-washed and air-dried without any measurable loss. The iodine-131 content is determined in a γ-spectrometer using the 0·364 MeV photopeak. With a 3 in. × 3 in. sodium iodide (Tl activated) crystal, the detection limit is 10 μμc. with a precision of 15 per cent if counting is for 50 min.

Because of our success in removing iodine-131, we compared the reproducibility of the method to our standard radiochemical procedure[7] after spiking milk with iodine-131 in the ionic form. Details are given in Fig. 1.

Our technique agrees well with that described by Boni[8], and we have found the method reliable over a period of several months.

Splitting of Uracil Dimer by High-energy Electrons

Thymine or uracil in frozen aqueous solutions are readily converted into their dimers by ultra-violet irradiation[1–3]. Using ion exchange chromatography on 'Dowex 1', the dimers of both pyrimidines-2-^{14}C were prepared in chromatographic homogeneous forms. Recently, it was established by us that thymine dimer is easily split into thymine monomer by irradiation with high-energy electrons[4].

During the experiments recorded here an aqueous solution of uracil dimer (120 μg/ml.) was irradiated with 100 kr. electrons of 34 MeV at room temperature. After exposure to β-rays 30 per cent of the radioactivity of the uracil labelled with carbon-14 were shown to be situated in monomer uracil by the method of paper chromatography. By the same dose of 200 kV X-rays the splitting effect could not be found at this high quantity, while the damages of the monomer molecules rose significantly. Similar results have recently been published for X-irradiation of thymine dimer[5].

The easy splitting of thymine dimer may be of some biological importance in connexion with the restoration of damaged cells. Dimerization of pyrimidines in the nucleic acid chain is also believed by some authors to cause lethal or mutagenic effects by ultra-violet irradiation[1,6]. Therefore, several experiments were carried out on the reactivation of ultra-violet irradiated bacteria, and our preliminary results indicate a rise in survival of ultra-violet irradiated bacteria after irradiation with low doses of electrons.

BIOLOGY

Infertility in Mice caused by Nutritional Stress before Mating

Mice from which all food was withheld for 48 h from the end of the third to the end of the fifth day after finding copulation plugs did not litter[1]. The fasting appeared to depress hypophyseal gonadotrophic function, causing degeneration of the deciduomata and secondary embryonic death. Although embryonic death is an important cause of infertility, failure of fertilization and death of ova before nidation are also commonly involved in the pathogenesis of mammalian infertility. This communication reports the results of attempts to influence the viability of the ovum by imposing nutritional stress before ovulation. As it was essential not to inhibit œstrus and mating a shorter period of starvation was given.

In a series of 5 experiments, 8–12-week-old virgin mice of the Sydney White strain were caged in groups of 2, 3 or 4. 166 were fasted for 24 h 3–8 days after caging. Male mice were introduced, one per cage from 3 days before to 3 days after the fasting period. 61 comparable mice were not fasted and were kept as controls and were mated at a similar time after caging the females. Water was always

freely available. Mice were examined daily after introduction of the bucks for evidence of mating. This was found in 102 starved and 49 control mice within 5 days of the end of the fasting period and in the case of control mice 6 days after introduction of the males either by the finding of copulation plugs or spermatozoa in vaginal smears. Treated mice were grouped according to the time 0–5 days which elapsed between the end of fasting and finding spermatozoa or copulation plugs. The mated mice were allowed to complete the expected gestation period and the numbers of mice littering were noted. The results are given in Table 1.

Table 1. A Comparison of Fertility (Littering Rates) of Mice Fasted for 24 h at Six Different Starvation-Mating Intervals and of Non-Starved Mice

		102	44	43
7	Control—no starvation	49	28	57

Comparison of the sum of classes numbered 1, 2 and 3 with the sum of 4, 5 and 6 and with 7 showed highly significant differences ($\chi^2 = 9{\cdot}71$, $P = < 0{\cdot}01$ and $\chi^2 = 6{\cdot}68$, $P = < 0{\cdot}01$).

These results indicate that fasting for 24 h significantly reduced the littering rates of the females mated one and two days after the end of the fast.

I thank Miss A. E. Dowell for assistance and Mrs B. Clarke for statistical analysis.

The Bill-snap Reflex : a Feeding Mechanism in the American Wood Stork

In the course of field observations of the American wood stork (*Mycteria americana*) in Florida, the birds were seen to capture fish habitually from water so turbid or choked with vegetation that the use of visual cues was improbable. In such feeding behaviour, a stork typically inserts its partially open bill into the water, moves the bill slowly from side to side, and walks forward. Submerged vegetation is sometimes stirred with one foot and the wing on the same side is flashed open, presumably to startle concealed fish into the open bill. When a fish makes contact with the bill, the mandibles are quickly closed with considerable force. These feeding techniques have been previously described[1–3].

Using two captured wood storks, we measured the time required for closure of the bill after stimulation of the lower mandible. One of the birds was then temporarily deprived of frontal vision, and its ability to capture fish by means of the bill-snap reflex was examined.

Measurements of the reflex speed were accomplished by using a piezoelectric crystal to which a stiff wire had been attached. The electrical output of the crystal was led to one channel of an electronic switch the output of which triggered the sweep of an oscilloscope. The second channel of the electronic switch contained a 500 c.p.s. timing signal obtained from a General Radio model 1304*B* oscillator calibrated against line frequency. Single sweeps of the oscilloscope beam were photographed, and measurements were made from the photographs of the time elapsing between stimulation of the lower mandible and closure of the bill. The unrestrained birds were blindfolded during the measurements and had been deprived of food for two or three days prior to the experimental session.

Examination of the oscilloscope photographs revealed that nine trials were usable from one bird and 16 trials from the other. Many trials were discarded because the birds snapped the sensing device repeatedly, causing multiple sweeps of the oscilloscope beam to appear on the photograph. In a few trials there were no responses. Only those photographs showing a single sweep and a clear indication of the elapsed time were used. A typical oscilloscope trace is shown in Fig. 1, and results for the two storks are given in Table 1. Additional measurements of the speed of the bill-snap reflex, made on two other days with the same birds, gave similar values.

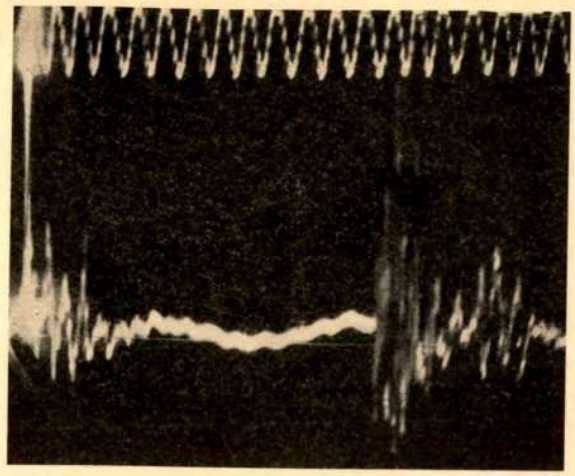

Fig. 1. Typical oscilloscopic record of bill-snap reflex. Upper trace: timing signal, 500 c.p.s.; lower trace, output of piezoelectric cartridge. The initial stimulus triggers the sweep of the oscilloscope; bill closure is indicated by the onset of the signal at the right of the lower trace

Table 1. Bill-snap Reflex Measurements on Two Wood Storks, *H* and *E*

Statistic	*H*	*E*
Mean response time	24·7 ms	25·3 ms
Standard error	0·92	1·07
Range	20–27 ms	19–32 ms
No. of trials	9	16

In triggering the bill-snap reflex, the lower mandible was found to be more sensitive to stimulation than the upper mandible. The portions of the tomia which generally come into initial contact with the fish are very horny, and, although no histological examination was made, we think it unlikely that any tactile receptors are present there. It seems more likely that the bill closure is a myotatic reflex, occasioned by a stretching of the jaw musculature when the bill is depressed[4].

Restriction of frontal vision in one bird was effected by gluing segments of blackened ping-pong balls to the denuded cranium in such a way that the bird was deprived of at least the central 75° of visual field. The blinders were attached while the stork was anæsthetized with ether; 3 h elapsed between recovery from anæsthesia and the experimental observations. The birds were allowed to feed together in a round wading pool, approximately 2 m in diameter and 25 cm deep, to which they were accustomed. Thirty to forty live fish, 10–15 cm long, were placed in the pool. Feeding behaviour of the two birds was observed and motion pictures were taken.

Visual restriction had little effect on the general feeding behaviour of the stork and no effect on its ability to capture fish. The partially blinded bird captured fish as well as its normal companion, and clearly utilized the reflex closure of the mandibles in response to stimulation by moving fish. The bird with normal vision showed some visual orientation to the prey; but actual capture was usually triggered by contact between bill and fish.

As Roeder[5] has suggested, 'strike times' of predators may have evolved to equal or better 'startle times' of potential prey. No startle times for typical wood stork prey (that is, fish or other lower vertebrates) were found in the literature. One of the quickest vertebrate startle responses appears to the eye blink after a strong auditory

stimulus in human beings, which has a latency of about 40 m.sec[6].

This feeding mechanism permits wood storks to secure food unavailable to species which locate their prey by vision alone. It also enables them to feed at night. Furthermore, this feeding technique is highly effective under the conditions of high fish density which prevail during the wood storks' breeding season in Florida[7].

Gigantism-inducing Factors in *Chlorella pyrenoidosa*

In a previous communication[1] we showed that when *Chlorella pyrenoidosa* is injected intraperitoneally into diabetic rats, the alga grows to twice its normal size. The causes of this phenomenon and its mechanism are the subject of this communication.

Since *Chlorella* is a facultative chemo-organotrophic alga which, according to Fogg[2], utilizes hexoses for preference, plasma glucose may well be the factor which causes gigantism. This, on being metabolized by the alga, might explain the disappearance of glycosuria in diabetic rats, as shown by us[3]. On the other hand, Lorenzen[4] maintains that, in certain conditions, temperature at 37° C causes an inhibition of division and an increase in the size of cells in *Chlorella*, and so the temperature inside the rat might also be the cause of gigantism.

50 ml. of a suitable culture medium for *Chlorella*[5] or 50 ml. of distilled water was placed in 250-ml. matrasses, and in both cases Pfanstiehl Lab. 16 mM glucose was added. Each matrass was sown with 10 mg (dry wt.) of the alga. The cultures were subjected to various conditions in order to examine the effects produced in them. Some matrasses were exposed to daylight, others to darkness; the temperatures ranged from 23° C to 37° C. Some of the matrasses exposed to daylight were subjected to a mixture of 95 per cent air + 5 per cent carbon dioxide. Others were not subjected to this atmosphere. The experiments, which lasted 96 h, were duly controlled without glucose. Every 24 h, the transformations undergone by the cells were observed through the microscope, the diameter of 50 adult cells in each matrass measured, and the average assessed.

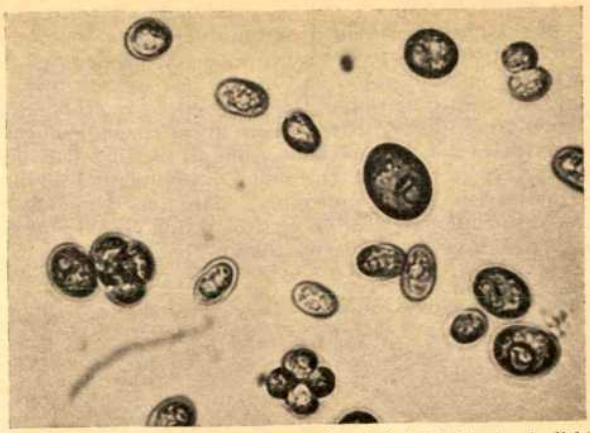

Fig. 2. Normal *Chlorella pyrenoidosa* cultivated at 23° C during daylight (× *c.* 800)

The adult cells of *Chlorella* increased in size in the presence of glucose and accumulated reserves, although their organization showed no change. The processes of division, sporulation, and growth of the culture were considerably attenuated. At the end of 72 h, changes appeared in the microscopic structure of the mother cells of the autospores, which were by now considerably larger in size than when checked (Fig. 1*a* and *b*). Autospores began to form, and at the end of this process each mother cell became a giant sporangium with a large number of autospores (Fig. 2), whereas the test tubes generally contained 4 autospores (Fig. 3). Light, temperature, and culture medium also exerted influences (Fig. 1*a* and *b* and Table 1). Subjection to the aforementioned atmosphere had no effect on the process of gigantism.

The effect of glucose having been proved, we investigated, under the same conditions and at the same concentration, whether the pentoses, hexoses, and disaccharides shown in Table 1 had a similar action on the glucose. Only fructose and mannose had the same effects as glucose and gave rise to equal findings. The other sugars showed no such action.

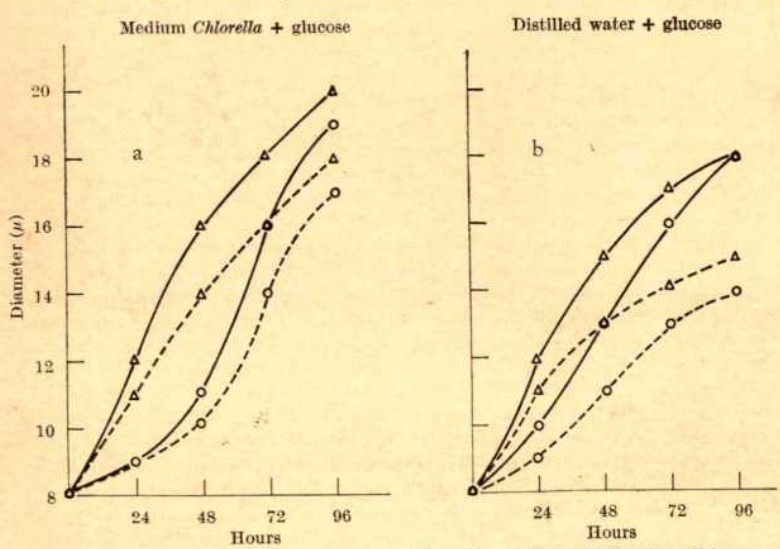

Fig. 1. Variation in diameter of *Chlorella* cells cultivated under different conditions. Daylight, —○—, at 23° C. —△—, at 37° C; darkness, – – ○ – –, at 23° C; – – △ – –, at 37° C

Sugars which stimulated gigantism caused a delay or an inhibition of cell division and sporulation; so that, according to Soeder[6] (since the sugars would increase the total concentration of the medium), cells larger than the normal ones would be originated and would contain a large quantity of reserve substances, which, later on, would cause giant sporangia with numerous autospores to appear. The fact that other sugars (ribose, xylose, galactose, sucrose, maltose, and lactose), which also increase the total concentration of the medium, do not promote gigantism is due to their not being metabolizable.

96 h after the beginning of the experiment the giant sporangia were detached from practically all the cells by centrifuging at 500 r.p.m. for 5 min; they were repeatedly washed with sterilized water, and sown in *Chlorella* mineral medium, but without sugar. A considerably more marked growth was observed than when sowing normal cells, for each sporangium released a large number of autospores. Previous treatment of the

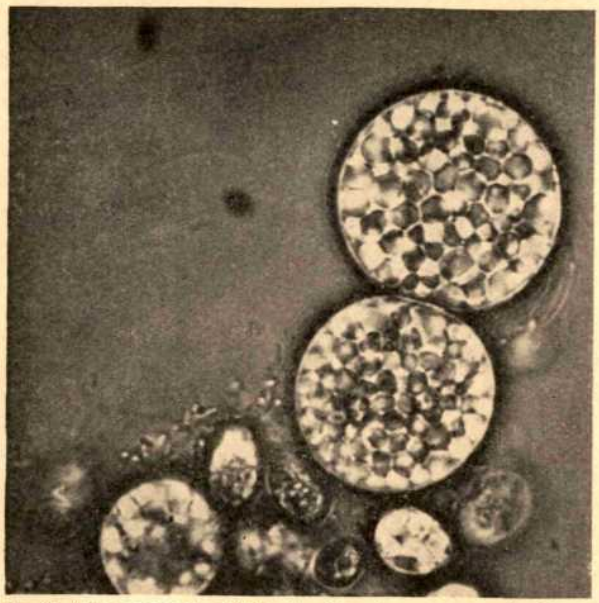

Fig. 3. Giant sporangia of *Chlorella* with autospores grown in glucose medium for 96 h in daylight at 23° C (× 1,200)

inoculum with gigantism-inducing sugars may be a good means of accelerating the growth of the culture in the examples presented here.

Table 1. Size (μ) of *Chlorella* Grown in Different Conditions for 96 h

Sugar added	Culture medium	Illumination	Temperature 23° C	Temperature 37° C
Glucose	Med. Chl.*	Daylight	19	20
		Darkness	17	18

Control†		Darkness	8	8

* Culture medium for *Chlorella*.
† No sugar added.
No. of experiments, four with different sugars.

In cultures in a mineral medium in which the inocula used were giant sporangia obtained through treatment with a sugar or isolated from the abdominal cavity of diabetic rats, we found, particularly at the beginning, a high percentage of adult forms with an average diameter of 12μ, of normal organization and appearance, which gave rise to sporangia having 8–16 autospores. We have not been able to count the chromosomes of *Chlorella*, but the fact that they slowly return to the normal size of the adult cell from which we started (8μ diam.) and the high percentage of giant forms lead us to believe that the phenomenon thus observed is not a polyploidism, but a trophic change caused by the sugars which are metabolizable to the alga (glucose, fructose, and mannose), from which state the cells regressed on encountering the sugar-less mineral medium, whereas they again became gigantic when returned to a medium containing an inducing sugar.

Influence of Bacillus Calmette-Guérin Infection on the Intensity of Homograft Reaction in Rats

In order to investigate the non-specific stimulation of the reticulo-endothelial system and consequences of this stimulation on the intensity of specific immune reactions it was decided to find out whether bacillus Calmette-Guérin (B.C.G.) infection would influence the rate and intensity of homograft reaction. Results have already shown[1] that the first set homograft rejection was markedly accelerated in B.C.G. infected rats. A similar effect was described by Balner, Old and Clarke[2]. They observed an accelerated skin graft rejection in B.C.G. infected female *C57BL*/6 mice grafted with isologous male skin.

Adult, 2-month-old, random-bred *Y* rats of both sexes weighing about 150 g were used. By exchanging a skin graft between random chosen animals it was shown that the median skin graft survival-time was in the first set 12·5 ± 0·06 days; the second set it was 8·0 ± 0·08 days. This relatively well-expressed difference between the first and second set homograft rejection was very suitable to determine the acceleration of the first set homograft rejection in B.C.G. infected rats. All experiments were done by using tail graft technique described by Bailey and Usama[3], the surface of the graft being about 1·0 cm × 0·5 cm. Rats were injected intracutaneously into tight region with 0·5 ml. of standard fresh prepared B.C.G. vaccine (Institute for Sera and Vaccines, Beograd).

Two hundred and twenty B.C.G. infected rats were divided in eight groups, each consisting of 25–30 animals and grafted with homologous skin on day 5, 8, 10, 15, 20, 25, 30 or 40 after infection. Each rat received a second skin graft 30 days following the first, both originating from the same donor. The control group contained 54 rats which were grafted only.

Table 1. Skin Homograft Survival Time in Rats infected with B.C.G. Vaccine on the Day Zero

First skin homograft Day of grafting	Median survival time	Second skin homograft Day of grafting	Median survival time
5	9·2 ± 0·05	35	8·1 ± 0·05
8	9·1 ± 0·05	38	8·1 ± 0·05
10	9·7 ± 0·05	40	8·2 ± 0·09
15	9·0 ± 0·09	45	7·8 ± 0·05
20	8·2 ± 0·06	50	8·0 ± 0·04
25	8·7 ± 0·04	55	8·1 ± 0·06
30	8·9 ± 0·04	60	8·0 ± 0·04
40	11·1 ± 0·04	70	8·0 ± 0·05
0 (control non-infected)	12·5 ± 0·06	30	8·0 ± 0·08

The results are shown in Table 1. As can be seen, B.C.G. infection exerted a marked acceleration of the first graft rejection. This effect was mainly expressed in the group grafted 20 days after B.C.G. infection. The homograft survival-time in that group came up to the values obtained in the second set reaction. The stimulation of the reticulo-endothelial system exerted by B.C.G. vaccine did not last for a longer period since 40 days following injection it revealed a tendency to disappear. It is obvious that no marked acceleration of the second graft rejection could be expected since the proximate second graft was placed 35 days after the injection, that is, at the time when the reticulo-endothelial system stimulation seemed, as already mentioned, to disappear. However, as no difference in the second skin graft survival-time was obtained when compared with controls, it was concluded that the second homograft does not depend on the intensity of the first set reaction. It is known that the difference between the first- and second-set homograft rejection is expressed more strongly in weaker antigenic differences in comparison with the strong ones. In the present experiments the differences between the first- and second-set homograft reaction was reduced by B.C.G. injection, thus simulating the strong antigenic differences. Zaalberg[5] obtained in *C57BL* female mice the first set

male skin graft rejection in a range of 12–91 (mean 45) days, having been in the second set in a range of 14–26 days. These last values correspond almost completely to the male first set skin graft rejection time obtained in B.C.G. infected *C57BL* female mice in the experiment performed by Balner *et al.*

From these results it can be deduced that the course and intensity of an immune reaction might be markedly dependent not only on antigenic differences but also on the functional status of the reticulo-endothelial system.

Fixation of Atmospheric Nitrogen by Root Nodules of *Comptonia peregrina*

Comptonia peregrina (L.) Coult. is a common shrub in the eastern part of North America. It is an important component in the shrub layer of the Pinetum banksianæ[1]. *Comptonia peregrina* and its variety *C. p. asplenifolia* (L.) Fern. have root nodules[2]. The structure of these has already been described[3].

In view of the similarity in structure between the nodules of *Comptonia* and those of *Myrica*, it was probable that the nodules of the former, like those of the latter[4], can fix atmospheric nitrogen. To prove this, the ability of *Comptonia* nodules to fix nitrogen-15 was investigated.

The test material used consisted of: (*a*) Parts of roots with nodules and with adhering soil particles, taken 2 h before the beginning of the experiment at the Botanical Garden, Munich. The root parts were placed in a glass-holder containing at the bottom a small layer of water (about 5 mm deep); (*b*) Parts of roots as in (*a*), but embedded in moist soil; (*c*) Parts of roots with nodules, collected 24 h before the experiment from the Botanical Garden, Darmstadt. During the experiment they were embedded in moist soil; (*d*) Moist soil, sampled in the rhizosphere of *Comptonia*, at prevailing soil moisture conditions; (*e*) As in (*d*), but after full water-saturation of the soil.

The material was transferred into a 'circulation system'[5], evacuated three times at 30 mm mercury and filled intermittently with argon with the purpose of expelling air. A gas mixture containing about 30 vol. per cent nitrogen and 20 vol. per cent oxygen in argon (with a nitrogen-15 content of 16·23 atomic per cent ± 0·068) was then introduced in the system. After six days the experiment was stopped. The nodules (with the adhering soil particles) were detached from the roots and the roots and nodules separately dried at 75° C in a vacuum oven. The soil, without roots and nodules, was dried at 105° C. Then the material was ground, the total nitrogen sampled by the Kjeldahl method, and the nitrogen-15 content determined with the aid of a mass-spectrograph (Atlas, CH_3/IS IV)[6]. The limit of the isotope-method used lies within an increase in nitrogen content of 0·01 per cent of the original amount.

Table 1 shows that fresh nodules (material *a* and *b*) fixed a remarkable amount of atmospheric nitrogen compared with the moderate increase in nitrogen content of the nodule-bearing roots. The soil showed very little or no increase in nitrogen content. The gain in nitrogen by the roots could be explained by the fact that they derived their additional nitrogen from the nodules. Nitrogen fixation by the soil-embedded root nodules (material *b*) was far more effective than that of material exposed to moist air (*a*).

Table 1

Material		Nitrogen content (% dry weight)	Nitrogen increase (% of original N)
a	Nodules	1·897	0·151
a	Roots	1·623	0·015
b	Nodules	2·597	2·224
b	Roots	1·702	0·578
b	Soil	0·354	0·013
c	Nodules	2·098	0·000
c	Roots	1·475	0·000
c	Soil	0·384	0·011
d	Soil	0·348	0·020
e	Soil	0·362	0·000

A greater elapse of time between collection and experimentation (material *c*) leads to a complete loss of the ability to fix nitrogen. It is possible also that the active nodules (material *a* and *b*) fix nitrogen only during the first phase of the 6-day experimental period.

These results confirm that root nodules of *Comptonia* can fix atmospheric nitrogen. A quantitative evaluation of the fixation capacity of intact plants cannot be derived from the results of the present experiment. Results previously obtained by Stewart[7] with *Alnus* would suggest that this capacity would be greater than that of isolated root parts.

In view of our results it is quite probable that *Comptonia peregrina* plays an important part in the nitrogen status of soils in the natural area of the species in North America.

We thank Dr. F. Schötz and W. Schacht of the Botanical Garden, Munich, for providing some of the plant material. We also thank the Deutsche Forschungsgemeinschaft for providing the means for carrying the isotope analysis.

Infection of Celery Seedlings by Viable Spores of *Septoria* spp.

Blight of celery caused by *Septoria* spp. was first definitely recognized in England in 1906 and afterwards was reported to spread rapidly over the country[1]. As early as 1910 it was known that the pycnidia of the fungus on the 'seed' contained spores which produced the disease when they were suspended in water and sprayed on to plants.

Chittenden[1], writing in 1914–15, gives reasons for suspecting that the seed was "the principal if not the only source of infection", and he claims to have been able to demonstrate infection of seedlings when infected seed was "sown in the ordinary way". Since then it has been commonly assumed that spores from pycnidia on the seed

infect young seedlings, but so far as I am aware there has never been a published description of a reliable method to show this. Mukkath and Wood[2] recently have suggested that celery seedlings may become infected by mycelium carried within the seed and that viable spores on the surface may be less important than previously assumed. On the other hand, Hewett[3] has found viable spores in an appreciable proportion of infected seed samples and considers these to be an "important potential source of disease outbreaks".

About 1914, 90 per cent of the commercial seed samples examined were found to be infected with *Septoria* spp. In 1957–58 Marshall[4] found 78·8 per cent infection, and among the present season's seed, that is, 1962–63, I have found only one sample out of 30 examined to be free of *Septoria*. Last year 17 out of 50 infected seed samples examined at Imperial College were found to have viable spores. The majority of these samples were less than one year old when tested.

The purpose of this communication is to describe a laboratory method for demonstrating that infected seed gives rise to infected seedlings and that infection can result from clean seed contaminated with viable *Septoria* spores. Here it may be noted that the same seed grown under ordinary greenhouse conditions never produced infected seedlings.

The method is as follows. A closely fitting glass cylinder, 7 cm diam. and 7 cm tall, is placed inside a tall 600 ml. glass beaker. The top of the ring is covered with muslin held in place by a rubber band, and the mouth of the beaker closed with a Petri dish lid after adding water up to the level of the muslin. The beaker is autoclaved at 15 lb. pressure for 20 min. When cool about 300 seeds (0·15 g) are placed evenly on the muslin and the beaker kept in the laboratory in the dark for one week. Thereafter it is placed on a laboratory bench 12 in. below 80-W fluorescent tubes switched on during 8 a.m.–8 p.m. daily. There is no reason for supposing that this method of illumination is critical. It is used mainly to ensure good growth of seedlings under laboratory conditions where the temperature is reasonably constant, about 20° C. Five weeks after sowing the seedlings are examined for infection by means of a stereoscopic microscope, magnification 20 times.

Three seed samples which were shown to have viable spores by the cultural method used in this laboratory[5] have been examined and the results set out in Table 1.

Table 1. Infected Seedlings obtained from Naturally Infected Seed

Seed sample	% pycnidial infection	% spore germination	No. of seeds sown (approx.)	No. of seedlings obtained	No. of infected seedlings
a	7	37	3,600	853	21
b	9	31	3,600	875	10
c	25	15	1,800	463	4
Control	7	0	3,600	822	0

With the same method no infected seedlings have been found if the seed was first treated with formalin or hot-water.

In another test clean seed which had also been treated with hot water was used. It was contaminated by steeping for half-an-hour in a thick suspension of *Septoria* spores (about 10 million per ml.) obtained from pure culture, and then allowed to dry over-night before placing in the beakers. The results are shown in Table 2.

It is clear, therefore, that seedlings can become infected by viable *Septoria* spores carried superficially on the surface of the seed, and in the absence of any other source of viable fungus. It has been shown that seed with pycnidia containing viable spores can also give infected seedlings and here too, presumably, it is the viable spores that are the source of infection. The possibility that the fungus on such seed can give infected seedlings in other ways is being investigated.

Table 2. Infected Seedlings obtained from Clean Seed contaminated with Viable *Septoria* Spores

Seed sample	No. of seed sown (approx.)	No. of seedlings obtained	No. of infected seedlings	Germination of spores washed from seed (%)
a	1,800	694	56	75
b	1,800	501	28	61
Control	900	382	0	0

I thank Dr. R. K. S. Wood for his advice.

Pathogenicity of *Streptomyces scabies* on Potato Tubers cultured *in vitro*

In potato breeding trials conducted here extensive investigations are required to determine the relative resistance of selected seedlings to the common scab disease caused by *Streptomyces scabies* (Thaxt.) Waksman and Henrici. The tissue-culture technique[1,2] for establishing a ready source of aseptic tubers potentially offers a rapid and convenient method for indexing their resistance and for studies on the host–parasite interactions. To evaluate this technique for studies on the common scab disease, tubers were produced *in vitro* using etiolated stolons[1] and aerial stem nodes of greenhouse-grown plants[3]. White's amended medium, containing 10 per cent sucrose for etiolated sprouts and 8 per cent sucrose for stem nodes, was used.

Tissue cultures were prepared from the following varieties: Green Mountain and Katahdin (scab-susceptible); Huron, Russet Burbank, and Cherokee (moderately resistant); Hindenburg, Richter's Jubel, Arnica and Ackersegen (highly resistant). Fifty tuber cultures of the Green Mountain variety and 20 tuber cultures of the remaining varieties were inoculated with a mycelial-spore suspension, in sterile distilled water, from a pathogenic strain of *S. scabies* (*L*272) which had been growing for 7 days on Czapek's agar. Because of the smooth surface of cultured tubers the inoculum tended to run off. Care was taken that all tubers had a drop of inoculum adhering to the surface. Cultures were maintained in the dark at 25° C.

In contrast to previous findings[2] no scab developed on tubers from any of the varieties. Occasionally a small lesion was noted on a few tubers from the susceptible Green Mountain. Similar results were obtained when this work was repeated using a second pathogenic strain of *S. scabies* (*L*28) as the inoculum.

These results suggested that either environmental conditions were unfavourable for disease development or the tuber surface in some way prevented invasion by the organism. The susceptible Green Mountain variety and the resistant Richter's Jubel variety were used in subsequent studies.

To test the effect of an altered environment the essentially chemically inert 'Vermiculite' was used as follows. 'Vermiculite' (fine) and water (100 : 60 (v/v)) were poured into a Petri dish, covered and sterilized at 121° C for 20 min. Enlarging tubers of 16-day-old cultures of Green Mountain and Richter's Jubel varieties were transferred, aseptically, to the sterile 'Vermiculite', inoculated, and covered lightly with the moist medium. The dish was covered and cultures were incubated at 25° C. Under these conditions 45 per cent of the susceptible Green Mountain developed scab within 10 days. Small lesions

were seen on a number of tubers within 3 days. With the exception of isolated instances no scab developed on the resistant Richter's Jubel variety. Where scab occurred the lesions were very superficial.

To determine the effect of an altered tuber surface on scab development, enlarging Green Mountain and Richter's Jubel tuber cultures were removed from the vials and soaked in sterile water for 5 h and in three concentrations of methanol for varying periods. Half of the tubers in the treatments were placed back in the vials and the remainder in moist 'Vermiculite'. Care was taken to prevent injury to tubers when making transfers. Cultures were inoculated (*L*272) and incubated as before. The water treatment enhanced scab development on both varieties. Green Mountain tubers in 'Vermiculite' showed some lenticel infection within 48 h and considerable scab in 4 days. 70 per cent were severely scabbed after 10 days. An occasional isolated lesion occurred on tubers placed back in the vials, but these took longer to develop and remained relatively superficial. 62 per cent of Richter's Jubel tubers in 'Vermiculite' developed scab within 10 days of treatment. Scab took longer to develop on this variety and the lesions were very superficial. There was no scab on Richter's Jubel tubers replaced in the vials.

When tubers were soaked for periods of up to 1 h in 10 and 25 per cent methanol and placed in the culturing media as described, 40 per cent of the Green Mountain developed scab in the 'Vermiculite' medium, whereas no scab developed on tubers replaced in the vials. There was no scab on the Richter's Jubel variety in either case. However, when tubers were soaked in 40 per cent methanol for 5 min severe scab developed on 80 per cent of the Green Mountain variety in 'Vermiculite', but very little on tubers replaced in the vials. With the Richter's Jubel variety 35 per cent of the tubers in 'Vermiculite' developed superficial scab. There was no scab on tubers in the vials.

In some instances the 40 per cent methanol treatment caused reddish-brown areas to develop on the tuber surface. The rose end was not usually affected. The Richter's Jubel variety showed less discoloration and when present occurred mainly at the lenticels. The discoloured areas did not appear to be more susceptible to infection.

These investigations suggest that the tissue culture technique fails to produce a set of circumstances that will permit the parasitic invasion of the scab organism. On the other hand, the placing of the tuber-bearing culture into a Petri dish of moist 'Vermiculite', and inoculating, does allow effective invasion. Additionally, it demonstrates degrees of resistances in that the invasion of the Green Mountain was accomplished while the Richter's Jubel remained clean. The washing of the cultured tubers, prior to their exposure to the pathogen in 'Vermiculite', apparently attenuates the resistance, permitting a greater invasion of Green Mountain and also the development of some symptoms in the Richter's Jubel. The results also suggest, after invasion, a differential vigour of the pathogens' establishment in that scab was less severe in the resistant Richter's Jubel.

The effect of the washing is not understood although it suggests the elimination or dilution of soluble native products or the alteration either of osmotic values or relative permeabilities. The 'Vermiculite' action may be strictly mechanical, providing a more uniform spread of the inoculum and a moister tuber surface. With refinement the technique may become an important adjunct to the present pathological assessment of breeding stock.

MICROBIOLOGY

Events associated with Development of Lipid Plaques on Plasma Agar

In a previous paper[1] we have reported that many strains of *Staphylococcus aureus* elaborate a diffusible extracellular lipolytic substance that produces visible lipid plaques on plasma agar, often in large amounts.

Careful examination of plasma agar preparations in which this substance is acting show that its effects occur in a stepwise fashion and that plaque formation is actually a later manifestation of this phenomenon. This communication describes these sequential changes leading to the formation of such lipid plaques.

Ten per cent plasma plates were prepared by adding 2·5 ml. plasma from 24 different normal human ACD bloods to 22·5 ml. trypticase soy agar at 48° C. Each plate was inoculated centrally with 1 loop of broth suspension from a slant of *S. aureus* Guy, incubated at 37° C for 5 days, and thereafter left at room temperature. To obtain agar segments containing the diffusible extracellular lipolytic agent, plain trypticase soy agar plates were inoculated centrally with *S. aureus* Guy, incubated at 37° C for 5 days and at room temperature for 2–5 weeks. Active sterile agar segments near the growth were cut out and placed on plasma plates. The plates were examined macroscopically and microscopically daily for 5 days and periodically thereafter.

After 1–2 days' incubation at 37° C, a finely dispersed precipitate appeared in an area 0·5 cm wide surrounding the growth of *S. aureus*. The diameter of the precipitate-containing area increased at the rate of 0·2–0·3 cm a day. Of the 24 plasmas tested, marked lipid production was consistently observed in 1–2 days in 7 plasmas; moderate production of lipid occurred during 3–6 days with 11 plasmas, and slight or no lipid production was seen in 6 plasmas.

In discussing the microscopic observations in this work, we have divided the plasma agar into three zones parallel to the plates: the bottom face of the agar (*a*); the central area (*b*); and the surface of the agar (*c*).

After 1 day at 37° C, the bottom face of the agar (*a*) was crowded with numerous minute particles in an area extending out 0·3 cm beyond the periphery of growth. At this time there were no changes in zones (*b*) or (*c*). By the second day, on the bottom face (*a*), elongated particles (Fig. 1) had developed, apparently from agglomeration of the smaller particles observed on the previous day; and round, dense bodies appeared throughout in the middle zone (*b*). By the third day, numerous closely packed clumps of round particles (Fig. 2) were seen on the bottom face (*a*), and, in zone (*b*), additional dense bodies (Fig. 3) had developed. In zone (*c*) lipid plaques (Fig. 4) had appeared about 0·5 cm away from the *S. aureus* growth overlying the area containing sub-surface particles.

After 4–5 days' incubation, the clumps in zone (*a*) became large, irregular and filamentous; the dense bodies in zone (*b*) increased in number and size, and more plaque material was produced on the surface of the agar. In plates made with plasmas which yielded the largest amount of plaque material, the changes occurred so rapidly and concurrently (often 24 h or less) that the sequence of changes described above was not seen. Similar changes were observed when active sterile agar segments were used instead of living *S. aureus*.

Raised spherical, refractile globules were seen in and near the surface of lipid plaques (× *c.* 80). These increased in size and number when plates were placed at 4° C for 1–2 h (Fig. 5). Such globules were always associated with lipid plaques and had a definite configurative relationship to them, developing at points from which the plaques appeared to originate.

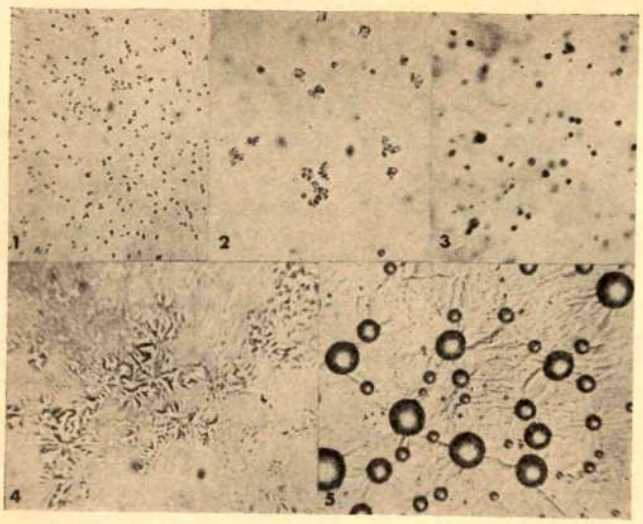

Fig. 1. All plates (× *c.* 80) were previously inoculated centrally with *S. aureus* Guy.

(1) Incubation, 37° C. 2 days. Elongated particles at bottom face of agar. Zone *a*. (2) Incubation, 37° C. 3 days. Clumps of round particles at bottom face of agar. Zone *a*. (3) Incubation, 37° C. 3 days. Dense bodies in middle zone *b*. (4) Incubation, 37° C. 3 days. Delicate lipid plaques on surface zone *c*. (5) Incubation, 37° C. 5 days. Lipid globules in and near surface plaques

Using micromanipulation techniques, it was possible to enter some of the larger globules with a very fine capillary and withdraw what proved to be liquid contents. When cooled below 4° C, this material solidified, remelting readily with slight warming. It was immiscible with water, but dissolved readily in various organic solvents. The very minute amounts of material that could be collected in this manner were subjected to several microchemical tests using reagents such as rhodamine *B*, α-*cyclo*dextrin, bromthymol blue, 2,7-dichlorofluorescein and sudan black *B*[2,3] and to chromatographic procedures described previously[1]. The results of these tests together with the observed physical properties indicate that the liquid content of these globules is lipid in nature, and that it consists primarily, if not entirely, of octadecenoic acid. Efforts are now being made to collect enough of this material for more exhaustive analysis.

The observations reported here show that the initial events associated with the eventual production of surface lipid plaques occur on a microscopic scale in the depths of the medium. The first sign of activity is the formation of minute particles on the bottom face of the agar. There follows a sequence of events as we have described resulting eventually in the visible surface plaques. There is a direct relationship between the number of sub-surface particles and the amount of lipid produced on the surface. Further, the sub-surface particles invariably spread out within the agar in advance of and just below the outward moving surface lipid. Thus in screening *S. aureus* strains for the ability to liberate free lipid from media, evidence of such activity can be obtained within 24 h simply by microscopic examination of the depths of the agar whereas surface lipid may not be visible for several days.

It has been shown that certain strains of *S. aureus* elaborate extracellular material that liberates octadecenoic acid and other lipid materials from plasma[1]. The presently available information indicates that the particles visible within the agar and the surface lipid material are the water-insoluble cleavage products produced by this lipolytic substance. It is presumed that lipolytic enzymes are involved; the elaboration of such enzymes by strains of *S. aureus* has been recorded[4] although little is known of their nature or action. Studies to investigate further the nature of this lipolytic substance, or substances, and of the products formed are now being initiated.

PSYCHOLOGY

Development of Alcohol Preference in *BALB/c* Mice

McClearn and Rodgers[1] have reported differences in alcohol preference of various strains of mice tested on a two-bottle choice between water and a 10 per cent ethanol solution. The *BALB/c* strain is one of several identified as having low alcohol preference. Adult mice of this strain were found to avoid the ingestion of ethanol solutions in concentrations as low as 2·5 per cent[2].

During subsequent investigations, it was found that young *BALB/c* mice voluntarily ingested a considerable amount of 10 per cent ethanol solution. The discrepancy between this observation and the earlier ones might be due to developmental changes in preference for alcohol; the *BALB/c* mice examined initially were approximately 1 year old, while the age of those displaying some preference for alcohol varied from 6 to 9 weeks. The work recorded here was therefore undertaken in order systematically to investigate the possible developmental changes in alcohol preference of this strain.

The *BALB/c* mice were obtained from the Cancer Research Genetics Laboratory of the University of California, Berkeley. Males were used for the first investigation, and males and females for the second. The animals were caged individually and were provided with tap water and a 10 per cent ethanol solution in 25-ml. graduated cylinders. The position of the cylinders was changed every 3 days so as to avoid the establishment of possible position habits. Daily readings were made of the liquid consumption, and a daily preference ratio was computed as the volume consumed from the ethanol solution divided by the total consumed from both cylinders. A mean of the daily preference ratios for a two-week period was calculated for each animal. Food ('Diablo Labration') was available *ad lib.*

The first observations were made on independent samples of mice at various ages of 3–20 weeks. It should be noted that the animals were production stock, and the ages were known only within ±3·5 days. The results of the first study are shown in Fig. 1. The number

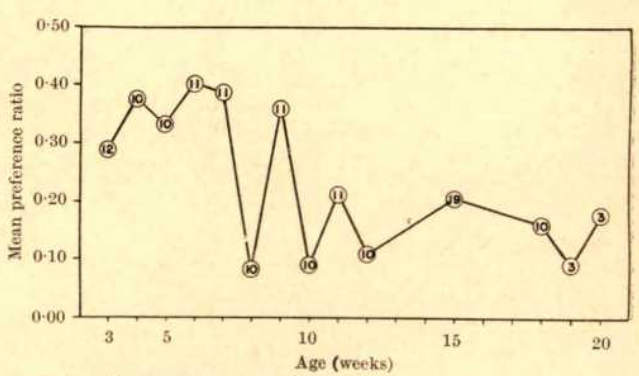

Fig. 1. Alcohol preference of *BALB/c* mice as a function of age. (Age shown as at beginning of 2-week test period)

indicated at each data point represents the number of animals tested at that particular age. The results clearly indicate that the younger animals show higher mean preference for alcohol than do the older animals. Indeed, there is a strong suggestion of an abrupt threshold. It is quite likely that the rather discrepant results at the 8th and 9th weeks may be explained by the inexact information concerning age. If this is so, it would indicate that the threshold occurs some time during the 9th week of life.

The second investigation involved 8 female and 16 male *BALB/c* mice. Alcohol preference was measured on the same animals twice, once at 4 weeks and again at 16 weeks of age. Ages were determined exactly for animals of this experiment. The testing and scoring procedures were exactly the same as in the first study. During the interval between the first and second test, the animals were housed in groups of 3 or 4, and had only water available as their drinking fluid. Food was given *ad lib.* The results of the second investigation are shown in Fig. 2.

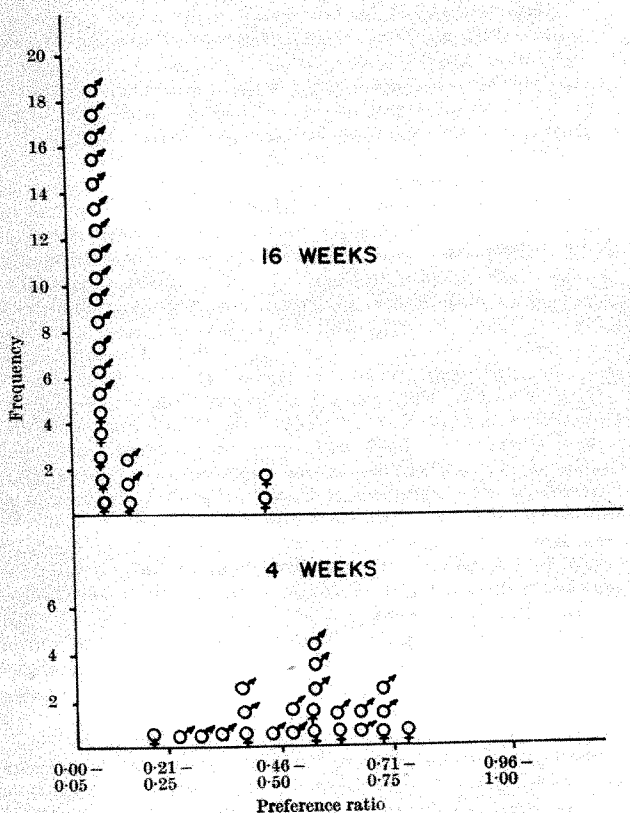

Fig. 2. Alcohol preference of a group of *BALB/c* mice measured at 4 and again at 16 weeks of age. (Age shown as of beginning of 2-week test period)

Since inspection revealed no sex differences, the data for both sexes were analysed together. The mean preference ratio was 0·50 at 4 weeks of age and 0·12 at 16 weeks of age. The difference was found to be significant ($P < 0.005$) by the Wilcoxon test[3]. The low mean alcohol preference at 16 weeks of age is in accord with the results obtained by McClearn and Rodgers[1]. These results indicate that exposure to ethanol during the high acceptance period does not result in an 'addiction' which persists into the adult, non-preferring phase. It remains to be determined if continued exposure to ethanol throughout the intervening period would result in a similar decline in preference.

The higher voluntary intake of ethanol solution by young *BALB/c* mice does not appear to be due to a simple failure of discriminative capacity. Inspection of the daily records indicates that preference for ethanol solution developed only gradually over the 2-week period, and there was very little intake of ethanol solution in the first few days. Thus, the mean preference ratio of the second week of testing was considerably higher than that of the first week.

These two investigations, one cross-sectional and the other longitudinal, agree in demonstrating a striking change with age in the alcohol preference of *BALB/c* mice. The available evidence indicates that the change from alcohol-accepting to alcohol-avoiding is an abrupt one. Investigations of correlated changes in anatomical, physiological, or biochemical processes might provide useful suggestions as to the nature of the mechanism producing the strain difference in alcohol preference of adult mice.

Maintenance of High Accuracy without Augmented Feedback

We would like to direct attention to results obtained from a keyboard training experiment.

Using a 10-key keyboard, subjects (18 postmen aged 30–40 years) were taught a logical association between pairs of keys and letters of the alphabet, except *Q*. The nature of the association is irrelevant here; but one might note that instruction required four 45-min sessions spread over two days, to achieve error-free response to letters called out by the instructor. This initial instruction was given to classes of six men, and in subsequent practice there were three men in a class.

After the first two days of alphabet learning, subjects copied town names from typed lists, receiving four 5-min runs morning and afternoon for 8 days. Speed and accuracy were equally stressed, but whereas the amount copied during each run was obvious to the subjects, they were given no information at all concerning errors, the output from the keyboard being in the form of punched tape. The speed and accuracy achieved during practice (all runs and subjects meaned daily) are shown in Fig. 1.

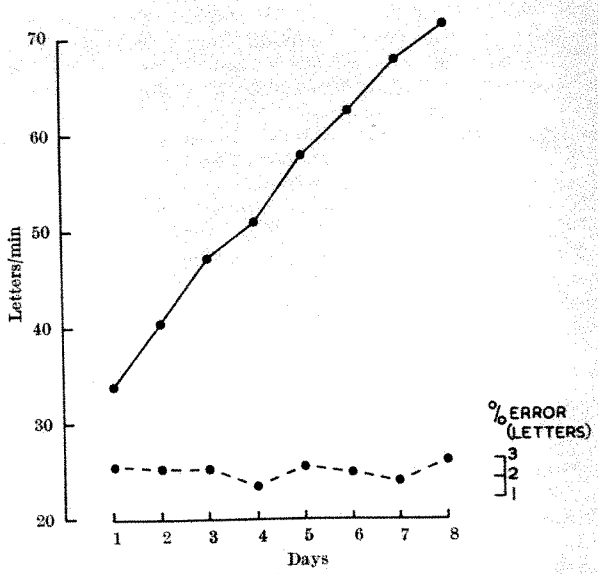

Fig. 1. Speed and accuracy of keying

It should be noted that the code used, while logical, was more complex than that usually utilized in laboratory tasks, and the task as such was a very close approximation to a real-life situation. Because of this, the results obtained are of particular interest. It was shown that subjects were able to improve steadily in speed without loss of accuracy, although they were not given immediate augmented feedback[1]. This finding lends support to a hypothesis which states that augmented feedback can be withdrawn as soon as a vocabulary has been learned to the point when, given sufficient time, subjects can produce the items without errors. From this moment onwards subjects are held to be able to provide sufficient intrinsic feedback to keep performance at a high level of accuracy. The hypothesis, therefore, provides a perfectly simple criterion for the point during training at which augmented feedback can be withdrawn. Since this point may well be reached much earlier than is generally assumed, the design of training schedules and devices may not have to be as complex as some current writers appear to think[2].

VIROLOGY

Experimental Transovarial Transmission of Kyasanur Forest Disease Virus in *Haemaphysalis spinigera*

Transovarial passage in ticks has been investigated for several viruses of the tick-borne encephalitis complex. Russian workers have reported that Russian spring–summer encephalitis virus can pass transovarially in *Ixodes persulcatus*, *I. ricinus*, *Dermacentor silvarum* and *Haemaphysalis concinna*[1]. Benda[2], working with *Ixodes ricinus* and the European strain of tick-borne encephalitis in Czechoslovakia, demonstrated transovarial transmission in only 6 per cent of ticks, while Smorodintsev[3] in the U.S.S.R. reported that it occurred in 5–25 per cent of ticks. In an investigation confirming transovarial transmission of tick-borne encephalitis virus in *I. ricinus*, Rehacek[4] found that it occurred in 2 per cent of ticks infected by feeding and in 20 per cent of ticks infected by inoculation after feeding. Laboratory studies with a third member of the complex, Kyasanur forest disease virus, and its vector *Haemaphysalis spinigera* are reported here.

In a preliminary experiment, 8,713 larvæ, the progenies of 79 laboratory-infected *H. spinigera*, were processed in 92 pools for virus and all were negative. These females had moulted from larvæ and nymphs which had fed on 3–5-day-old chicks infected with Kyasanur forest disease. In each case infection in the tick was confirmed by isolation of virus in mice after deposition of eggs.

To determine whether the virus could pass transovarially if given the opportunity to reach the ovaries of the ticks without going through the alimentary canal, 35 unfed adult female *H. spinigera* were inoculated in the membranous portion of the joint between the coxa and the trochanter of the third leg with a fine needle drawn from 2-mm capillary tubing. The inoculum consisted of approximately 1,500 adult mouse LD_{50} of strain *G* 11338 of the virus which had undergone three mouse brain passages and a further five intra-muscular passages of infected blood in 1-day-old white leghorn chicks. It is presumed that the virus entered the hæmocœle directly and that there was no injury to any internal organ.

One week after inoculation, the ticks were released on a month-old calf. Twenty-nine of the 35 ticks engorged and laid normal fertile eggs. When tested after oviposition, these ticks were all positive for virus, and virus was also found in their excreta.

The larvæ from each tick were then divided into two groups of 500–1,000 each, and the first group, in pools of 200, was inoculated intracerebrally into adult mice. Virus was recovered from larvæ of 17 of the 29 ticks.

The second group of larvæ was released on 1-day-old white leghorn chicks to examine their ability to transmit the virus by bite. The 29 chicks used were bled twice, on the third day and again on the fifth day after release of the larvæ, and the blood was inoculated intracerebrally into adult mice. Virus was found in the blood of 16 chicks. The larvæ fed on these chicks were held for 10–15 days at 25° C and 90–95 per cent relative humidity to moult into nymphs. The nymphs of 26 groups were processed in pools of 50–100 each, and virus was isolated from 11 groups.

In this experiment the proportion of infected females capable of transmitting virus transovarially to larvæ was considerably greater than that reported by Rehacek[4]. Nevertheless, although larvæ were processed in fairly large pools, the proportion of pools negative for virus seemed to indicate that the number of infected larvæ produced per female was very small.

Since transovarial transmission had occurred in ticks infected by inoculation into the body cavity but not in ticks infected by feeding, it became necessary to investigate whether in the latter group virus was absent from the body cavity and the hæmolymph. A total of 140 female *H. spinigera*, previously infected in the larval and nymphal stages by feeding on infected chicks, was divided into seven groups of 20 each. The legs of the ticks were carefully detached either with fine scissors or with forceps; all instruments had been sterilized and the same instrument was not used for more than one tick. The detached legs and the 'de-legged' bodies of each group were inoculated separately into adult mice, and virus was recovered from all pools, both of legs and of bodies. This result would seem to indicate that virus is present in the hæmocœle of ticks infected by feeding.

Further work is necessary before these results can be used for interpreting field data. In particular, the experiments with progenies of ticks infected by feeding must be repeated under a greater variety of conditions. The potentiality of transovarial transmission of Kyasanur forest disease virus in *H. spinigera* has, however, been established.

We thank Dr. T. Ramachandra Rao, director, Virus Research Centre, for his critical and helpful advice throughout the investigation.

Synergistic Effect of 2-(α-Hydroxybenzyl)-benzimidazole and Guanidine on Picornavirus Reproduction

Both 2-(α-hydroxybenzyl)-benzimidazole (HBB) and guanidine are specific and potent inhibitors of picornavirus multiplication[1]. However, in virus-infected cell cultures maintained for a prolonged period in the presence of either compound, drug-resistant mutants regularly emerge[2–4]. Recently it has been shown that mutants of poliovirus resistant to either HBB or guanidine exhibit only a small degree of reciprocal cross-resistance[5,6].

Combined treatment with HBB and guanidine was, therefore, expected to have a greater suppressive effect on virus reproduction than either compound alone. This proved to be the case in experiments with 'Coxsackie B3' and 'ECHO 5' viruses[5,6].

The large effect of combined treatment suggested, however, that it was not solely due to inhibition of mutants exhibiting limited cross-resistance, but that, in addition, HBB and guanidine acted synergistically.

The following experiment was carried out to test this possibility. 'Coxsackie A9' virus was grown in primary monolayer cultures of rhesus monkey kidney cells in a single infectious cycle[7]. HBB and guanidine hydrochloride, either alone or in combination, were added to the cultures at the end of the viral adsorption period, that is, 1 h after virus inoculation. The cultures were collected 7 h later and virus yields were determined by the plaque technique[7].

Table 1 shows the result of a typical experiment. HBB, 19 μM, or guanidine, 219 μM, had no effect on virus reproduction when given alone. 2·25-fold higher concentrations of HBB or guanidine reduced the virus yield 50–300 times. Yet still higher concentrations of either compound were required to suppress virus reproduction completely. On the other hand, 19 μM HBB and 98 μM guanidine, when given in combination, inhibited virus growth completely. The complete inhibition cannot be explained on the basis of inhibition of mutants resistant to one compound but sensitive to the other, since neither compound was used at inhibitory concentration.

Table 1. Synergistic Effect of HBB and Guanidine on the Multiplication of 'Coxsackie' A9 Virus

Compound	Concentration μM	Virus yield: Plaque-forming units/ml.	Virus yield: Treated, per cent of untreated control
None	—	$3·0 \times 10^8$	100
HBB	19	$3·0 \times 10^8$	100
	43	$6·5 \times 10^6$	2·2
	98	$1·6 \times 10^5$	0·05
Guanidine	219	$3·5 \times 10^8$	117
	493	$1·1 \times 10^8$	0·4
	1,110	$1·4 \times 10^5$	0·05
HBB + Guanidine	19		
	98	$2·0 \times 10^5$	0·07

Two other combinations (29 μM HBB + 219 μM guanidine; 43 μM HBB + 98 μM guanidine) were also found to inhibit virus reproduction completely, and even 9 μM HBB + 98 μM guanidine had some effect (72 per cent inhibition).

The mechanism of the synergistic effect of HBB and guanidine on virus multiplication is not known at present. Both compounds inhibit the production of virus-induced RNA polymerase[8], and of viral RNA and coat protein[7,9–12]. It may, therefore, be hypothesized that the compounds affect different aspects of the virus-specific reaction sequence which leads to the synthesis of viral RNA.

From a practical point of view, combined use of both compounds holds promise for the treatment of virus diseases.

This investigation was supported by a grant from the U.S. National Foundation.

ANTHROPOLOGY

Selection Intensity in Brazilian Caingang Indians

It is becoming increasingly clear that if we wish to understand the biological evolution of man we must examine in detail the selective pressures and breeding structures of human populations which are in different stages of cultural development. Crow[1] suggested a relatively simple method for measuring selection intensity in man. This communication describes the results obtained with Crow's method collected from among the Caingang Indians living in the State of Rio Grande do Sul, Brazil.

These Indians have already been subjected to a series of investigations which aim at understanding the evolutionary forces which shaped their present genetic constitution[2,3]. Details about the location of these groups and their demographic structure were described in a previous paper[2].

Table 1. Selection Intensity in Caingang Indian Populations of Rio Grande do Sul, Brazil

Population	N_1	$\bar{x}$	Vf	N_2	pd	Im	If	I
Ligeiro	24	4·5	16·4	262	0·439	0·783	0·810	2·2
Cacique Doble	15	5·2	10·5	156	0·327	0·486	0·389	1·1
Guarita	46	7·4	14·4	768	0·410	0·695	0·263	1·1
Nonoai	49	6·0	14·4	681	0·417	0·715	0·400	1·4

N_1, No. of women studied whose age was 40 or more; $\bar{x}$, average No. of live births per woman; Vf, variance in progeny number due to fertility; N_2, total No. of live births (women of all ages); pd, premature deaths (died before the reproductive age); Im, mortality component; If, fertility component; I, index of total selection intensity.

The results are shown in Table 1. The average number of live births per woman aged forty years or more varied from 4·5 to 7·4. The corresponding variance was 10·5–16·4. The mortality before the reproductive age ranged from 32·7 to 43·9 per cent. From these results the mortality and fertility components of the index of total selection intensity, Im and If respectively, can be calculated. Im varied from 0·486 to 0·783; If from 0·263 to 0·810. The extreme index values obtained were 1·1 and 2·2. Spuhler[4] has recently reviewed the information concerning these variables in ten tribal populations. The index of total selection intensity varied in these groups from 0·6 to 3·7. The values presented here, therefore, are in the lower half of the range observed. This shows that the Caingang are not subjected to too stringent selective pressures, despite the heavy mortality before the age of reproduction observed among them. In five of the ten populations reviewed by Spuhler the mortality component was higher than the fertility one, while in the five others the opposite occurred. Among the Caingang three of the populations presented higher Im and only one higher If values. Mortality is still very important in determining the gene frequencies in these Indian groups. Total selection intensity is about the same in Cacique Doble, Guarita and Nonoai, but, due to fertility differentials, shows a two-fold increase in Ligeiro.

This work was supported in part by Rockefeller Foundation grants and by U.S. Public Health Service research grant *GM*-08238.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TUTORIAL ASSISTANT IN PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (August 6).

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (mathematician, with a first- or second-class honours degree in mathematics or applied mathematics with experience in the application of numerical analysis and digital computers, and preferably some knowledge of numerical methods), to lead a section of the team providing a mathematical service to the Laboratory—The Director, National Engineering Laboratory, D.S.I.R., East Kilbride, Glasgow, quoting Ref. E/AQ/030 (August 7).

LECTURERS or ASSISTANT LECTURERS (3) IN PHYSICS at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 8).

DIRECTOR (with a university degree with specialization in zoology, preferably in mammalology, and administrative experience, particularly in a museum or kindred institution) OF KAFFRARIAN MUSEUM—The Director, Kaffrarian Museum, King William's Town, C.P., South Africa (August 10).

POST-DOCTORAL FELLOW (chemist or physicist) IN SPECTROSCOPY IN THE DEPARTMENT OF CHEMISTRY, to work on the application of lasers to Raman Spectroscopy in collaboration with Dr. D. A. Long—The Registrar, University College of Swansea, Singleton Park, Swansea (August 10).

TECHNICIAN (with City and Guilds Certificate, mechanical and constructional aptitude, conversant with laboratory and field techniques and with the routine running of a research biological laboratory, preferably in a marine setting, and able to supervise a small technical staff) in the Dove Marine Laboratory (University of Durham)—The Director, Dove Marine Laboratory, Cullercoats (August 10).

ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER (with a degree, Dip. Tech., or H.N.C. in electronic engineering or equivalent, and a good knowledge of electronic circuitry including pulse and high frequency techniques) IN THE BASIC PHYSICS DIVISION, to work on the development and maintenance of equipment for fundamental research in microwave and radio-frequency spectroscopy—The Director, National Physical Laboratory, D.S.I.R., Teddington, Middlesex (August 12).

ASSISTANT EXPERIMENTAL OFFICER (with a degree in a natural science or an appropriate Dip.Tech. or H.N.C., and preferably training or interest in statistics or applied physics), to join a team working in the field of building design and town planning—The Director, Building Research Station, D.S.I.R., Garston, Watford, Hertfordshire (August 12).

LECTURER (preferably with an interest in control systems, analogue computers, electrical power or electrical machinery) IN ELECTRICAL ENGINEERING—The Registrar, The University, Sheffield (August 12).

SENIOR LECTURER or LECTURER (physical chemist, suitably qualified to teach to degree level in physical chemistry for the B.Pharm. honours degree and research experience in physical chemistry applied to pharmaceutical or related topics) IN PHARMACEUTICAL CHEMISTRY (Physical Aspects)—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (August 12).

ASSISTANT EXPERIMENTAL OFFICER (graduate), to assist in aphid investigations at the Entomological Field Station, Cambridge—The Director, A.R.C. Unit of Insect Physiology, Department of Zoology, Downing Street, Cambridge (August 13).

ASSISTANT PROFESSOR IN THE DEPARTMENT OF ZOOLOGY, to participate in the cell biology programme and to teach proto-zoology, cytology, or a related subject at the senior undergraduate level—Dr. C. V. Finnegan, Department of Zoology, The University of British Columbia, Vancouver 8, B.C., Canada (August 15).

ASSISTANT LECTURER (preferably with postgraduate research experience in one of the following fields: polypeptides, nucleotides or polysaccharides) IN ORGANIC CHEMISTRY—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (August 16).

LECTURER or ASSISTANT LECTURER (with a good honours degree, and preferably a special interest in plant physiology or biochemistry) IN BOTANY—The Registrar, King's College (University of London), Strand, London, W.C.2 (August 16).

POST-DOCTORAL RESEARCH FELLOW IN CHEMISTRY at Wollongong University College, The University of New South Wales, for work on structural problems relating to natural products, chiefly alkaloids, likely to possess pharmacological activity—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (August 16).

TUTORIAL STUDENT (graduate, or about to graduate) IN THE DEPARTMENT OF BIOPHYSICS, to read for a higher degree and give a limited amount of assistance by demonstrating—The Registrar, King's College (University of London), Strand, London, W.C.2 (August 16).

EXPERIMENTAL OFFICER IN THE DEPARTMENT OF CHEMISTRY in the Faculty of Science, to be concerned with preparative work involving the synthesis of inorganic molecules containing isotopically labelled atoms—The Registrar, The University, Manchester 13 (August 17).

LECTURER IN STATISTICS; and an ASSISTANT IN MATHEMATICS in the Faculty of Science, Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee, Scotland (August 17).

LECTURER (with a good honours degree in science or technology, preferably some industrial experience, and interested in research work) IN PAPER SCIENCE—The Registrar, The Manchester College of Science and Technology, Sackville Street, Manchester 1 (August 17).

POST-DOCTORAL RESEARCH FELLOW IN THE DEPARTMENT OF NATURAL PHILOSOPHY, St. Salvator's College, for work on high resolution electron spin resonance at X-band and Q-band frequencies, and/or for work on the measurement of spin-lattice relaxation times by the use of microwave techniques—The Secretary, The University, St. Andrews, Scotland (August 17).

LECTURER (dental, medical or science graduate with bacteriological experience) IN DENTAL BACTERIOLOGY in the Turner Dental School—The Registrar, The University, Manchester (August 24).

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics or engineering or equivalent, and preferably some familiarity with computer logical design), to work in collaboration with other physicists studying gamma-ray dosimetry and measurement of neutrons and of radioactivity—The Director, National Physical Laboratory, D.S.I.R., Teddington, Middlesex, quoting Ref. 121.YV (August 24).

SENIOR RESEARCH OFFICER (Soil Chemist) (with a Ph.D. degree or post-graduate research experience of equivalent duration and standard, preferably in soil chemistry, supported by satisfactory evidence of research ability) IN THE DIVISION OF LAND RESEARCH AND REGIONAL SURVEY, Commonwealth Science and Industrial Research Organization, Canberra, to undertake chemical investigations on New Guinea soils with particular reference to the clay fraction—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 618/135 (August 24).

SENIOR LECTURER (preferably qualified to lead and develop research in applied geophysics or the physics of thunderstorms) IN THE DEPARTMENT OF PHYSICS, University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 25).

LECTURER IN PATHOLOGY at the Western Infirmary—The Secretary of University Court, The University, Glasgow (August 26).

SENIOR BIOCHEMIST (post-doctoral, with experience of peptide structural analysis), for research on brain peptides; and a RESEARCH BIOCHEMIST or HISTOCHEMIST, to work on problems of neurological metabolism in tissue cultures in the Department of Pathology—The Registrar, The University, Leeds 2 (August 26).

ASSISTANT LECTURERS (2) (with a medical or scientific qualification) IN BACTERIOLOGY—The Registrar, The University, Manchester 13 (August 31).

LEADER (with an established research reputation in one of the relevant scientific disciplines (biochemistry, physiology, microbiology, physics or chemistry), the ability to lead a research group and guide younger workers, and preferably experience in meat research) IN MEAT RESEARCH in the Division of Food Preservation, Commonwealth Scientific and Industrial Research Organization, Cannon Hill, Brisbane, Australia, to advise the Chief of the Division on the development of new basic and applied projects and the expansion of existing activities—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 305/71 (August 31).

SENIOR BIOCHEMIST IN THE DEPARTMENT OF CHEMICAL PATHOLOGY, United Liverpool Hospitals, to assist with the Department's routine work and research programme, particularly in relation to the metabolic ward now reaching completion at the Liverpool Royal Infirmary—The Secretary, United Liverpool Hospitals, 80 Rodney Street, Liverpool 1 (August 31).

SENIOR LECTURER or LECTURER (graduate in physics, chemistry, biochemistry or engineering, with experience of research in food processing) IN FOOD SCIENCE IN THE DEPARTMENT OF AGRICULTURAL SCIENCES at the School of Agriculture, Sutton Bonington—The Registrar, The University, Nottingham (August 31).

RESEARCH STUDENT IN GEOGRAPHY—Secretary of the Graduate School, London School of Economics and Political Science (University of London), Houghton Street, Aldwych, London, W.C.2 (September 6).

CHAIR OF MATHEMATICS; and a CHAIR OF PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR. 05G (September 7).

POST-DOCTORAL RESEARCH FELLOW IN INORGANIC CHEMISTRY, for the study of magnetic properties of transition metal complexes in association with work carried out by Prof. Ballhausen in Copenhagen—The Registrar, The University, Manchester 13 (September 7).

LECTURER (graduate in physics or agricultural science) IN SOIL PHYSICS IN THE DEPARTMENT OF AGRICULTURAL CHEMISTRY, Waite Agricultural Research Institute, University of Adelaide—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 9).

READER IN PURE MATHEMATICS; a SENIOR LECTURER IN MATHEMATICAL PHYSICS; a LECTURER IN ORGANIC CHEMISTRY; and a LECTURER IN ELECTRICAL ENGINEERING at the University of Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 9).

ASSOCIATE PROFESSORS/SENIOR LECTURERS IN MICROBIOLOGY AND PARASITOLOGY; and SENIOR LECTURERS/LECTURERS IN PATHOLOGY (2) BACTERIOLOGY; VIROLOGY; MYCOLOGY; and PARASITOLOGY at Massey University College of Manawatu, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Massey University College of Manawatu, Palmerston North, New Zealand (New Zealand and London, September 15).

CHAIRS IN BIOLOGICAL SCIENCE (2) at Massey University College of Manawatu, Palmerston North, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

PROFESSOR OF THEORETICAL PHYSICS at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 15).

SENIOR LECTURER and a LECTURER IN PHYSICS at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 15).

ASSISTANT CONSERVATOR OF FORESTS (over 30, a university degree in forestry, and preferably at least ten years experience as a Forest Officer in South-East Asia, preferably Malaya) IN THE FOREST DEPARTMENT, North Borneo—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting T/RC.324/107/01.

BIOCHEMIST (Senior or Basic grade) at the Midland Centre for Neurosurgery and Neurology, Holly Lane, Smethwick—The Group Secretary, West Bromwich and District Hospital Management Committee, Edward Street, West Bromwich.

CHEMIST (male, with an honours degree in chemistry or equivalent qualification, and not less than two years postgraduate experience or training) IN THE DEPARTMENT OF AGRICULTURE, Tanganyika, for research work on coffee, including soil and plant analysis connected with nutritional problems and soil survey work—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting T/RC.213/145/05.

DEMONSTRATOR IN ZOOLOGY—The Registrar, University College of Wales, Aberystwyth.

ELECTRONICS PHYSICIST or ENGINEER (preferably university graduate, but candidate with equivalent qualifications and suitable experience will be considered) IN THE DEPARTMENT OF CHEMISTRY, to take charge of a workshop concerned with the development and construction of new electronic equipment for research, and for the maintenance and repair of electronic instruments and equipment—The Bursar (B.49), The University, Sheffield 10.

EXPERIENCED CYTOLOGY TECHNICIAN (qualified in vaginal cytology), for routine investigations on obstetric and gynæcological patients—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1.

GRADUATE BIOCHEMIST or CHEMIST, to work on aspects of the biosynthesis of phospholipids in the nervous system with Dr. G. B. Ansell—The Head of the Department of Experimental Neuropharmacology, The Medical School, The University, Birmingham 15.

LABORATORY ASSISTANTS (2) (preferably G.C.E. "A" level, H.N.C. or equivalent), to join a research team investigating the control of breathing in man—Dr. I. P. Priban, c/o Superintendent, Autonomics Division, National Physical Laboratory, Teddington, Middlesex.

MICROBIOLOGIST (graduate in any of the biological sciences considered) IN THE BACTERIOLOGY LABORATORY—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1.

PHYSICIST and a PHYSICAL CHEMIST (of Ph.D. standing, preferably with research experience in a related field) to join a team engaged in basic, long-term research into the photoconducting behaviour of organic materials—The Director, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian.

POSTDOCTORAL FELLOW IN PHYSICAL CHEMISTRY, to work on a fundamental study of thermal diffusion in binary liquid mixtures under the direction of Dr. H. J. V. Tyrrell—The Registrar, The University, Sheffield 10.

RESEARCH ASSISTANT (preferably with a Ph.D. and an interest in the electrophysiology of nerve fibres), to work on a programme of study of nervous tissues *in vitro*—Prof. C. E. Lumsden, Department of Pathology, The University, Leeds 2.

RESEARCH ASSOCIATE (honours graduate, preferably with experience of cytology), to work on human chromosomal aberrations in the Medical Genetics Laboratory of the Institute of Child Health—Prof. Douglas Hubble, Institute of Child Health, Francis Road, Birmingham 16.

RESEARCH FELLOW (with an honours degree in chemistry, biochemistry or agricultural chemistry or in a closely allied field), for work in the field of protein nutrition—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 63/11.

RESEARCH OFFICER, HEAD OF THE ANIMAL HUSBANDRY DIVISION (under 50 years of age, with a good honours degree, preferably in sciences which include animal physiology and biochemistry, and experience in initiating research programmes in the field of animal husbandry and management) in the East African Agricultural and Forestry Research Organization, Muguga, Kenya, to be responsible to the Director for the initiation and carrying out of research programmes on important problems of animal management in East Africa—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. C1/R.7217/383/01.

SCIENTIFIC OFFICER (male or female, with an honours degree in science or biology) IN THE LABORATORIES OF THE BLOOD TRANSFUSION SERVICE—The Director, Regional Blood Transfusion Service, Roby Street, Manchester 1.

RESEARCH SCIENTIST (with a degree in a scientific subject and an interest in the physical properties of powders), for fundamental investigations into flour milling processes; and an ORGANIC CHEMIST, to join a small team working on chemical modifications of starch—The Director of Research, Cereals Research Station, Research Association of British Flour Millers, Old London Road, St. Albans, Herts.

SENIOR LECTURERS or LECTURERS (with a first- or second-class honours degree or equivalent in any branch of mechanical engineering and, if possible, member of one of the major professional bodies) IN MECHANICAL ENGINEERING, to teach at university level—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire.

SENIOR TECHNOLOGIST (with sound training and experience in electron microscopy and ultra-microtomy, and preferably with a science degree or diploma) IN THE MEDICAL RESEARCH UNIT—Prof. C. E. Lumsden, Department of Pathology, School of Medicine, The University, Leeds 1.

TECHNICIAN (expert in preparing thin and polished sections and competent to take charge of other technical duties) IN THE DEPARTMENT OF GEOLOGY—The Chairman, Geology Department, University of Ottawa, Ottawa, Ontario, Canada.

TECHNICIAN, for clinical research in the Respiratory Function Laboratory—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1.

TISSUE CULTURE TECHNICIAN, for work in the Radiobiology Unit—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

FOR PERIODS UP TO

1 hour
24 hours
7 days

The

Histokinette

stays on the job

Diagnostic reports to hand hours earlier than they would be with manual processing and in far greater numbers—the release of a valuable technician for other duties . . . these are the outstanding advantages of the Histokinette Automatic Tissue Processing machine. Once the Histokinette has been put into operation, it will *without supervision* go through the entire cycle of fixation, dehydration, impregnation in wax, or alternatively can be set up for the washing or staining of tissues. It can handle large numbers of specimens at the same time and while staff is off duty—speed up almost any technique by ensuring quicker and more thorough penetration by reagents.

A 24-hour clock is fitted as standard. Change over to 1 hour or 7 day cycles (*the latter of great value in double embedding and bone decalcification techniques*) is simple and rapid.

Histokinette special features include :—

- Up to 24 hours delayed start
- Double processing capacity
- One or more motor members and baskets
- Unbreakable tissue basket and containers

The Hendrey Histokinette is in general use at home and overseas

. . . to quote a few in U.K.

CLASSIFIED ADVERTISEMENTS

are charged at 12s. for the first line and 6s. per line thereafter. Lines in capitals or containing words in capitals 12s. per line. Semi-displayed £4 16s. per single column inch. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clement's Inn, Strand, London, W.C.2. Telephone: HOLborn 4743. Telegrams: Textualist, Estrand, London.

APPOINTMENTS VACANT

MEDICAL RESEARCH OFFICER (MALE/FEMALE)

required by the West African Institute for Trypanosomiasis Research, Kaduna, Northern Nigeria, for research on human trypanosomiasis. The appointment will be on contract for one tour of 12 to 18 months with a prospect of re-engagement for a further tour by mutual consent. Commencing salary will be according to qualifications and experience in the scale £1,248, rising to £2,388 a year. Gratuity (liable to tax) at rate of £150 a year. Free passages. Liberal leave on full salary. Candidates must possess a registrable medical degree and have two years' postgraduate research experience preferably in immunology, protozoology, or tissue culture techniques. Women must be single.

Apply to Crown Agents, 4 Millbank, London, S.W.1, for further particulars, stating age, name, brief details of qualifications and experience, and quoting reference M3/54323/NF.

MATHEMATICIANS

required by

MINISTRY OF AVIATION

for a wide range of work including operational research, air traffic control problems, advanced computer techniques, computer programming, statistics, information theory, assessment studies for rocket motors, theoretical work in solid state physics, evaluation of aircraft and weapons, flight dynamics, development of mathematical models and simulators. Possible locations include London, Farnborough (Hants), Malvern, Amesbury (Wilts), Westcott (Bucks). Appointments in grades of: Senior Scientific Officer, £1,438 to £1,772; Scientific Officer, £791 to £1,309 (somewhat higher rates apply in London). Qualifications: first- or second-class honours degree is required, and for Senior Scientific Officer (minimum age 26) at least three years postgraduate research experience. Starting salary according to experience. Superannuation under F.S.S.U.

Application forms and booklet from Ministry of Aviation, Est.2/3.A.3, Room 516, The Adelphi, John Adam Street, W.C.2, quoting HC/2D/0899.

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Lecturer in Chemical Metallurgy in the Department of Metallurgy of the Faculty of Science. Applicants should possess a good honours degree in metallurgy or chemistry or equivalent qualifications and have experience or special interests in one of the following fields: extraction metallurgy, alloy thermodynamics, electrochemistry, high temperature chemistry or structural inorganic chemistry. Salary on a scale from £1,250 to £2,150 per annum, initial salary according to qualifications and experience. Membership of the F.S.S.U. and children's allowance scheme.

Applications should be sent not later than August 31, 1963, to the Registrar, The University, Manchester, 13, from whom further particulars and forms of application may be obtained.

VETERINARY RESEARCH OFFICER (male/female) required by the West African Institute for Trypanosomiasis Research, Northern Nigeria, for research work, etc., in the Veterinary Section. Time allowed to follow own lines of research. The appointment will be on contract for one tour of 12 to 18 months with a prospect of re-engagement for a further tour by mutual consent. Commencing salary will be according to qualifications and experience in the scale £1,248, rising to £2,388 a year. Gratuity (liable to tax) at rate of £150 a year. Free passages. Liberal leave on full salary. Candidates should be members of the Royal College of Veterinary Surgeons (or its equivalent) and must have at least two years experience in research. Women must be single.—Apply to Crown Agents, 4 Millbank, London, S.W.1, for further particulars, stating age, name, brief details of qualifications and experience, and quoting reference M3/54322/NF.

LAING

INORGANIC and PHYSICAL CHEMISTS

For the field of study which includes silicate chemistry, involving the hydrothermal reactions of lime and silica, and fundamental studies in the utilization of pulverized fuel ash and other basic raw materials. These studies are linked with the demand for new and improved building materials in the industry.

The vacancies offer opportunities for personal contact with other research organizations, manufacturers and practical application within the group. Applicants should be between the ages of 28 and 38, with minimum qualifications of B.Sc. or A.R.I.C.

Apply in writing, giving brief details, to:

Group Personnel Manager (WM. 75)
John Laing and Son Limited
London, N.W.7

NATIONAL RESEARCH COUNCIL (CANADA)

requires a

MATHEMATICIAN-PROGRAMMER

for

NRC COMPUTATION CENTRE

DUTIES: This position at the NRC Computation Centre involves the analysis and programming of problems originating in the various scientific and engineering divisions of the Council. Duties may include the supervision of junior programmers.

QUALIFICATIONS: Applicants should hold an honours degree in mathematics from a recognized university. Preference will be given to those holding a higher degree and possessing experience in programming and numerical analysis.

SALARY: Initial salary up to $10,000 per annum depending on education and experience.

Applications should be made to the Employment Officer, National Research Council, 100 Sussex Drive, Ottawa, 2, Canada.

In reply, please quote File ER-282.

D.S.I.R.

HYDRAULICS RESEARCH STATION

Wallingford, Berks

Principal Scientific Officer

HYDROLOGIST

This research establishment requires a man or woman to take charge of a new and growing Hydrological Research Unit, undertaking extensive research on the effects of land management on water balance and other hydrological topics.

QUALIFICATIONS: Normally first- or second-class honours degree in civil engineering, physics or mathematics; considerable experience in hydrological or hydrometeorological research essential.

SALARY SCALE: £1,894 to £2,646. Starting salary may be above the minimum.

Promotion prospects. A pensionable post. Write Civil Service Commission, 23 Savile Row, London, W.1, for application form, quoting **S/5640/63.** Closing date August 23, 1963. Candidates who have already applied need not do so again. (3)

EDITORIAL ASSISTANT REQUIRED FOR Metallurgical Abstracts. Scientific qualifications essential for searching literature. French and/or German desirable. Commencing salary £800 to £900 a year. Pension scheme.—Apply, giving details of qualifications and experience, to the Editor, Institute of Metals, 17 Belgrave Square, London, S.W.1.

VICTORIA UNIVERSITY OF WELLINGTON

NEW ZEALAND

Applications are invited for the following appointments:

Senior Lecturer and Lecturer in Botany. These are new posts and are not being allocated in advance to particular branches of the subject; applicants may apply for both. All applicants should be willing and able to take some part (if required) in the conduct of the general first-year course, particularly practical classes.

Lecturer in Geography. Applicants should have specialized knowledge of social and economic conditions in New Zealand with an adequate background in mathematical and statistical geography and, if possible, first-hand experience of work in the fields of social or economic development in New Zealand.

Lecturer in Geology. Preference will be given to an applicant who is qualified in the fields of optical mineralogy and igneous and sedimentary petrography, but applications from candidates qualified in other fields will be considered.

The salary scale for a Senior Lecturer will be £1,750, rising to £2,000 per annum, and for a Lecturer will be £1,250, rising to £1,700 per annum. The initial salary will be determined according to the qualifications and experience of an appointee.

Approved fares to Wellington will be allowed for an appointee, his wife, and his dependent children. In addition, actual removal expenses will be allowed within specified limits.

Further particulars and information as to the method of application should be obtained from the Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close, in New Zealand and London, on August 31, 1963.

UNIVERSITY OF LIVERPOOL

DEPARTMENTS OF BOTANY AND ORGANIC CHEMISTRY

Applications are invited from candidates holding a Degree in Biological Sciences, Higher National Certificate, or equivalent qualification for the post of Technical Assistant to join a group investigating microbiological aspects of fungal biosynthesis. Candidates should have had previous training in microbiology. Salary according to age and qualifications within the range £540 to £605 per annum. A supplement to basic salary is payable for possession of an approved qualification.

Applications, stating full academic qualifications and experience, together with the names of two referees, should be received as soon as possible by the Registrar, The University, Liverpool, 3, quoting reference number CV/374/N.

MANAGEMENT PERFORMANCE

BRITAIN'S failure to maintain a challenging place in the race for productivity has, in turn, been ascribed to lack of early enough awareness by the Government of what was involved, lack of competence by industrial management, and lack of appreciation by the nation at large that the balance of trade has so changed that we can no longer live on our 'invisible' earnings. The setting up of the National Economic Development Council at the beginning of 1962 was itself admission that the Government was at last taking national economic planning seriously, while recent moves to set up a senior institution concerned with management education is evidence that there is now considerable support for the belief that the quality of management can be considerably improved by some basic education and training.

The amount of management training being carried out in institutions of all kinds is still far too small, however, and this and other projected developments will have little effect on management performance for some time. Many of the older managers will be little affected by any of the proposals for improving management education, and they form the bulk of present-day management. What can be done to help them to improve their own performances ?

The majority of these men are individuals who left school at the 'elementary' or grammar school stage and whose further education has been confined to what they could pick up in evening classes and on the job. Despite much criticism, these managers have served industry well and many of them possess considerable business shrewdness and practical awareness of what management involves and requires. Over the past decade plenty of advice has been showered on them, much of it of that 'gimmicky' kind which temporarily fills the pages of industrial journals and then quickly disappears. The need for better communications, 'brain-storming', 'posting' of problems, joint consultation, management by exception, management by objectives—all have merit but all have suffered through too much advocacy and too grandiose claims. Courses and conferences of all kinds have been arranged for them, and, while many of the more specious have not justified the claims of their organizers, others have at least been useful in persuading some managers to take a more empirical look at their own processes of management.

In this ephemeral world of panaceas three firm trends have emerged. The first is that enough experiment with management education has been carried out to justify all the recent moves to extend the quality and quantity of management courses on a secure and permanent basis. The second is that the invasion of mathematical concepts into industrial practice and procedure has only just begun. The use of operational research, network analysis, critical path planning and value analyses to improve stock and quality control, production scheduling, plant performance, distribution and warehousing and financial control have already reached the stage when production managers, engineers, marketing sales and financial management realize that their jobs can no longer be adequately carried out without substantial statistical support.

The third trend is of more recent origin and provides not only a continuing basis for the control of management performance but could also be the short term answer to the means of improving the country's productivity each year by the 4 per cent target which the National Economic Development Council regards as essential for healthy growth. Much management education and training has held little meaning for existing managers because they have failed to see the relevance to their particular jobs. They have failed to find yardsticks to measure their own performance and that of their colleagues, and the training provided has often appeared academic and remote. Even the annual appraisal of their performance during the year has seemed to consist of no more than a rigid mixture of generalization and exhortation.

Over the past few years some of our more enterprising organizations—not all big and not all private enterprise—have begun to develop training and development programmes for management based on their individual performances during an observed period. This is usually carried out as part of the annual appraisal procedure but bears no relation to the superficial way in which this is frequently performed in many institutions. Effective appraisals of management performance are carried out in considerable depth and in such a way that subjectivity is eliminated to the greatest possible extent. Although much of the early thinking about the control of management performance was initiated in the United States*, the detailed application to produce measurable results would appear to have been more successfully carried out in Britain. In a recent American work, which has attracted considerable attention†, the author gives useful advice about how systems and procedures in a business may be overhauled. His sections on the actual means of evaluating executive performance in the revision of these systems and procedures is superficial and sketchy and implies that, in common with other American authors, Leonard has failed to grasp the nettle. Drucker, on the other hand, has made a significant contribution to means of improving over-all business effectiveness and it would be useful if he would now turn his attention to improving individual management performance‡.

The true assessment of management performance and the building of an individual development programme cannot be begun unless the job is first clearly defined. In co-operation with the manager and his immediate chief, an experienced investigator needs to draw up a detailed job specification indicating the manager's duties and responsibilities, the tasks he undertakes to carry out those duties and responsibilities, the standards he is expected to reach to perform the tasks satisfactorily, and the controls which can be used to measure standards achieved against set tasks. Ideally, all standards should be capable of quantitative estimation but this is unlikely ever to be completely achieved. In practice, however, the fact that standards have been painstakingly set means that they are discussed with much greater objectivity during appraisal reviews.

This systematic approach to management performance has already produced some interesting results in those companies where it is being used. The company quickly

finds weaknesses in administration and procedures which it is able to eliminate; it receives suggestions from men whose views have not previously been sought about ways of improving its administration and procedures. Individuals taking part in appraisal procedure are encouraged when persistent difficulties are removed, while there is an all-round improvement in morale and teamwork when all-round improved performance begins to influence productivity. In the short term this seldom fails to occur and, over a longer period, can produce more than the National Economic Development Council target of 4 per cent without any increased capital expenditure. This is particularly so where appraisal of performance standards is followed by education and training programmes designed specifically to meet the needs of individual managers. In practice again, the needs of individuals have been followed by much more education and training on the plant than on external courses, and this in itself has led to a greater interest in means of improving productivity. While this systematic approach to management performance is still at an early stage, it offers one of the most fruitful ways of harnessing the practical knowledge and experience of existing managers which has yet been devised. Unfortunately, it requires skilled job analysts and men experienced in promoting in-plant education and training facilities and these are almost as rare as industrial mathematicians.

The main difficulty in introducing such a systematic approach to improved management performance is that it demands great skill in the handling of human relationships. Where the job analyst is a man employed by a company he should be drawn from the higher ranks. Sometimes it is more useful to use an experienced and independent 'outsider' who could profitably be a social research worker or a management consultant. Rosemary Stewart has directed attention to the valuable work which social research workers in industry can do but, surprisingly, she seems unaware of all that enterprising and critical managements are doing to improve their own performances§. Their efforts would well repay study by those who work in academic institutions. Industry is increasingly learning to make use of techniques being developed in academic institutions—selection processes, job analysis and the training of skilled operators, executive job grading for salary determination and so on—and many of the practical applications could well be used in the originating centres. The systematic approach to means of improving managerial performance which industry has adopted could profitably be used in other institutions.

THE MARK OF THE MASTER

Chromosome Marker

By K. R. Lewis and B. John. Pp. x+489. (London: J. and A. Churchill, Ltd., 1963.) 65*s*.

ALTHOUGH it is a quarter of a century since the publication of the last edition of Darlington's *Recent Advances in Cytology*, I still find it difficult to read a new book on chromosomes with a mind unbiased by comparison with the *Advances*. *Chromosome Marker* is no exception, and in fact the authors almost invite the comparison as they pay just and handsome dedication to their master. It is inevitable therefore that, despite the title which only became meaningful after reading much of the book, I had hoped for the much-needed synthesis of the past twenty-five years work on chromosomes. This is still to be written. *Chromosome Marker*, for example, does not make the near-synthesis that is now possible of the seemingly conflicting evidence on chromosome structure derived from tritium labelling, enzyme digestion, X-ray breakage and electron microscopy. Nor does it bring together the data on the vexed question of the mechanism of crossing-over. This was not the authors' intention.

The scope of the book, which is divided into four sections, includes a description of the normal behaviour and form of chromosomes in division, chromosome duplication and movement, and the mutational changes which occur in chromosomes. Full and useful accounts are given of the tritium-labelling experiments on duplication, on the action of the centromere in chromosome movement, and the morphological changes in some dipteron chromosomes which are related to cellular activity. Two sections of the book are devoted to types of visible chromosome markers of all kinds and their use in cytological and genetical experiments. A full and useful summary of Riley's work on the genetic control of chromosome pairing in wheat is given. All this is of considerable interest, and is the most valuable part of the book. It should be particularly valuable in the expanding field of human cytology where much of the plant and animal cytology is now being applied.

The final section of the book on the "Chromosomes in Evolution" invites comparison with the Darlington classic *Evolution of Genetic Systems*, and it is here that there is some disappointment. This may be because this aspect of genetics is one without a productive methodology. It has to rely largely on ideas and deduction, and therefore a limited advance is inevitable.

The book includes many quotations from the classics; these occupy a prominent place at the beginning of the chapters. It also has a short classification of the plant and animal kingdoms but it does not include a glossary of terms. Most of the scientific terms are explained when they are first used in the text. It is possible to find references in the index to Twain, Mark; Conan Doyle, Sir Arthur; and Carroll, Lewis; but terms such as 'desynapsis' or 'sympatric', used in the text, are not in the index. There is some unnecessary repetition in the book; for example, Chapter 2 begins, "All the characteristics of an organism are the result of interaction between the genotype and the environment. This is the primary postulate of genetics". The next but one chapter begins, "The phenotype is a product of interaction between the genotype and the environment. This is the basic premise of Genetics". Despite these and other small irritations, the book is one that should be read carefully by all who are interested in chromosomes and heredity. D. Lewis

COMPARATIVE PHILOSOPHY

Introduction to Comparative Philosophy

By P. T. Raju. Pp. xii+364. (Lincoln: University of Nebraska Press, 1962.) $7.50

STUDENTS in universities and readers in general have long been accustomed to books bearing such titles as "Comparative Anatomy" or "Comparative Religion", but "Comparative Philosophy" is novel. For this reason alone, *Introduction to Comparative Philosophy* is welcome. Moreover, in other ways, too, its appearance is significant. In a world wherein events make themselves felt everywhere with increasing speed, there is an obvious need for a wider understanding both between peoples as such and between individuals of different outlook and of varying

backgrounds. To achieve any measure of success in such an enterprise is not easy: nevertheless, Prof. Raju has made a notable contribution and what he has to say is deserving of very careful study. It should be observed at once that a strong point of the present treatment is the clear résumé provided at the end of every main section, setting out the essentials of each of the major philosophies —Western, Chinese and Indian. These summaries are again analysed and compared, thus achieving a particularly lucid methodology.

After a general introduction, the main theme is tackled as follows. First, Western philosophy and the struggle for the liberation of the outward; secondly, Chinese philosophy and human mindfulness; and thirdly, Indian philosophy and the explication of inwardness. A chapter on comparisons and reflexions, and a couple of appendixes complete the whole. These headings are themselves of value, as showing the way in which the author's mind works. He is a distinguished Indian scholar, and perhaps a little more introspective than most of us; yet he manages to keep his feet well on the ground and writes (for the most part) with the impartiality to be expected from a seeker after truth. The chronological table at the end is not without omissions which some authorities would regard as unfortunate, but as an example of its range, the Western column begins with Moses and ends with A. J. Ayer.

Prof. Raju is careful to point out that he is deliberately including Jewish philosophy as part of the Western tradition. This is sensible and makes easier the discussion of mediaeval thought (especially scholastic), and the development of a conscious thesis, more particularly by the great figures at the University of Paris, and the repercussions of their labours on the nascent seats of learning at Oxford and Cambridge, not to mention the influence of the friars.

These pages mirror the thoughts of a philosopher rather than those of a scientist or of a mathematician. That is sound enough, but it still leaves the feeling that a comparison of universal knowledge down the ages—and that is the subject under discussion—is only possible if some attention is given to the logicians, and the disciplines which are covered by them. It is true that China was defective here, but she was not without science and technology, which in their turn orientated her characteristic humanism. Needham's monumental volumes receive no mention at all, which is almost as much as to say that the "good life" of Confucius—and China's marked pragmatism—was untouched by her ability to invent and to apply. This in no way detracts from the importance of what the author has to relate, but it does mean that the reader must take his own steps to acquaint himself with all the facts before he can justly measure what has happened.

Indian philosophy is essentially concerned with salvation, and its emphasis is inward. There is no privileged intuition, and no heroes as such, and perhaps, consequently, no dogma. All this is well put, but the fact remains that had India produced a Plato or an Aristotle at the crucial moment in historical time, much might have been gained, and little lost.

Prof. Raju's erudition is enviable, and its scope remarkable. With an engaging modesty he realizes the limitations of language, and the possible loss of fine-structure due to translations. Nevertheless, his rendering of some parts of the Western tradition indicates something of a blind spot when faced with the relation between revelation and reason, or, if one so prefers, the recognition of philosophy as the hand-maiden of theology. Supposedly he has not absorbed the works of Gilson and Lessing (they are not included in the index), particularly the remark to the effect that the great truths of religion were not rational at the time of their revelation, but that some of them in any event were revealed that they might become so. In other words, St. Augustine and St. Thomas Aquinas did far more than merely re-edit Plato and Aristotle: at their hands something very important was added. It is entirely correct for Prof. Raju to maintain that he is not writing about religion, except incidentally. Yet he passionately wants philosophy to be a way of life for mankind (and the West has thwarted that aim to some degree by making it so much of a departmental study in most of its universities). If that is so, then the West may perhaps curb some at least of its outward tendency—as it is already doing—in an attempt not to frustrate reason, but to direct it where it may be most fruitful, strengthening the traditional humanism of China, and upholding the deeply felt naturalism of India.

The whole fabric of this book demonstrates the author's charity and his capacity to comprehend. Ratiocination may weary and faith become weak and errant, but *credo ut intelligam* still points the way for many people, and they, among others, could find their life illuminated by these admirable studies in comparative philosophy.

FLYSCH DEPOSITS

Sedimentology of some Flysch Deposits

A Graphic Approach to Facies Interpretation. By Dr. A. H. Bouma. Pp. xii+168. (Amsterdam: Elsevier Publishing Company, 1962.) 64*s*.

THE term 'flysch' was proposed by B. Studer in 1827 for a group of early Tertiary geological formations in the Pre-Alpine zone of Switzerland. It was quickly recognized that these formations had distinctive sedimentary characteristics, and the name came to be applied to similar rock-series of many different ages in many parts of the world. All these had in common an association with the later stages of major orogenic cycles; but no attempt at precise definition was made. Great impetus was given to the study of these rocks by the recognition, by Ph. Kuenen and his collaborators in the early 1940's, that marine turbidity currents were largely responsible for the formation of flysch; this theory at once provided an explanation for many of their sedimentary features, and a reason for their orogenic association. Since that time a voluminous literature has appeared in the journals of the world; the present volume is, however, the first 'hard-cover' text to appear in English. Since such a book might be expected to have a wider circulation among the 'non-specialists' than individual papers, and therefore to carry more authority, it must be pointed out that this volume represents no more than a thoroughly competent study of the kind carried out by many authors in many parts of the world, but which by accident of publication do not reach a wider public.

The major part comprises a description in detail of the Eocene–Oligocene flysch of the Peira-Cava area, 20 km north of Nice. No better introduction to the flysch could be obtained than from the magnificent, readily accessible sections here, and Dr. Bouma's text describes them lucidly. From their study he develops the hypothesis that each sandstone bed contains some elements of a sequence of rock types (named T_{a-e}, or sometimes, confusingly, T_1) each deposited by a different part of the turbidity current flow. He points out significantly that the base of this sequence may be missing (in regions distant from the source) or the top; but never the middle. Using the well-established methods of palæo-current studies he builds up a convincing picture of the palæogeography of the Alpes Maritimes. He then compares his rocks with a variety of others in Europe, and concludes that some are flysch and some are not, without giving a very clear indication of his criteria.

The first chapter is devoted to a description of a method for the production of 'graphic logs' for these sedimentary sequences. This is carefully worked out, and certainly

will facilitate accumulation of data. Dr. Bouma fails to convince that it is essential—the whole of the present volume can be perfectly comprehended without recourse to this system.

The glossary, as the text, sometimes gives the impression of being definitive where no general agreement among specialists exists—this particularly applies to the nomenclature of sole-markings. To some extent this is compensated by a full bibliography; read with an awareness of the complexities of this controversial subject, Dr. Bouma's contribution is very valuable indeed.

J. E. Prentice

PERPETUUM MOBILE

Tectonics

By Prof. Jean Goguel. English translation from the French Edition of 1952 by Hans E. Thalmann. (Series of Geology Texts.) Pp. viii+384. (San Francisco and London: W. H. Freeman and Company, 1962.) 70*s*.

THIS is a translation, with minor additions, of *Traité de Tectonique* which first appeared in 1952. We quickly realize just how much the geophysical sciences have advanced our knowledge of the Earth's crust during the last ten years. Since 1952, numerous publications have given the results of seismic exploration, gravity and magnetic surveys and heat-flow measurements at sea. We have had geophysical investigations of continental margins, deep-sea trenches and mid-oceanic rifts. A wealth of results in palæomagnetism has influenced our thinking about continental drift. Numerous advances in theoretical seismology have enabled a better probing of the crust and upper mantle. The use of electronic computing techniques has aided seismological investigations and the interpretation of geophysical surveys of granites, sedimentary basins and rift valleys. All these provide material for a re-appraisal of the tectonic history of the Earth. The most striking example is that the basic difference of the structure of oceanic and continental crust was not firmly established when this book was written. This must now surely be the starting point in structural geology, and it is sad that most university geology departments still teach the subject without recognizing the sea floor covers more than two-thirds the Earth's surface and whole *mémoires* have appeared on the results of oceanic exploration.

A translation of this kind is therefore necessarily outdated. However, the book contains much useful information and gives a profound coverage of classical thoughts and observations on the tectonics of the continental areas. There are excellent accounts of the observational powers of the geologist in investigations of erosion and deformation, morphology, stratigraphy, rock deformations and folding and faulting. There is a useful account of elementary geological mapping, including the use of bore-hole information and underground workings. There is a brief review of geophysical exploration and the geometric presentation of results and structural maps. All this is followed by a systematic description of basic structural forms and by various interpretations. Throughout, numerous examples provide adequate illustrations.

Prof. Goguel gives an impression of an ever-mobile Earth's crust. It seems that at almost any given time in geological history, field evidence can be produced from somewhere on the Earth's surface to reveal tectonic movements. Another phenomenon which is well brought out is the behaviour of the crust and mantle to stresses of different time constants. It is important to realize that the materials of the crust and mantle behave as solids to stresses for times of the order of 0·5 sec and as fluids to stresses for times of the order of 10^4 years. There is field evidence for this phenomenon and it is strange how little it has been considered in theories of crustal movements and continental drift.

Finally, what is the fundamental cause of tectonic deformations? The Earth could be cooling, and the crust reflects stresses due to shrinkage. The Earth could be warming up and the sialic crust dissipated due to expansion. The Earth could be alternately warming and cooling and the various tectonic deformations through geological time could be a consequence of both expansion and contraction. Lastly, the surface structures and deformations may be due to convection currents in the mantle. In recent years, this last-mentioned hypothesis has been fashionable and Jean Goguel gives it much attention. From recent work in palæomagnetism and exploration of the sea floor, especially the discovery of faults with horizontal displacements of the order of 1,000 km, mantle convection must be a strong possibility.

The book is well produced and carefully thought out. It also serves as a good introduction to continental geological literature. The translation is fair, a curiosity being that the translator seems to have given up translating metres to feet and inches after p. 14; a reminder that it is high time geology joined the other sciences in using the metric system.

R. W. Girdler

AUTOMATIC CONTROL

Automatic Control

An Introduction to the Theory of Feed-back and Feed-back Control Systems. By A. E. De Barr. (The Institute of Physics and the Physical Society Monographs for Students.) Pp. vii+118. (London: Chapman and Hall, Ltd.; New York: Reinhold Publishing Corporation, 1962. Published on behalf of the Institute of Physics and the Physical Society.) 7*s*. 6*d*. net.

Automatic Control Handbook

Advisory Editor, G. A. T. Burdett. Pp. xviii+864. (London: George Newnes, Ltd., 1962.) 90*s*.

Anatomy of Automation

By George H. Amber and Paul S. Amber. Pp. x+245. (Englewood Cliffs, New Jersey and London: Prentice-Hall Inc., 1962.) 60*s*.

THREE recently published volumes in the field of automatic control may broadly be described as dealing respectively with conventional linear theory, components and circuit techniques, and the philosophy of automation in industry.

Automatic Control is an inexpensive paper-backed volume in the Monographs for Students series in which is found a concise presentation of the basic linear theory of feed-back control systems, and a short chapter on non-linear systems. The author dispenses with the introduction to Laplace Transforms found in most standard text-books on this subject, and derives transfer functions and characteristic equations using only the differential operator. This approach leads to a demonstration of the dependence of the natural modes of the system on the roots of the characteristic equation that is not wholly satisfactory, but the saving in space is considerable and enables the concepts of circuit theory to be covered in the first chapter. Also introduced in this chapter of twenty-nine pages are Bode and Nyquist plots, segmented gain characteristics, and the result of the gain-slope theorem. In this last-mentioned connexion an error appears on p. 13 where minimum phase systems are described as having merely poles, rather than both poles and zeros, without positive real parts.

Closed-loop systems are introduced in the second chapter, which includes the frequency-response locus and Hall Chart, and in the third chapter a simple physical system is introduced together with an analysis of damping

methods and of velocity lag. In this chapter some small errors appeared in the diagrams where the impedances connected to the operational amplifiers should be directly connected, not through error detectors.

The stability problem is discussed in Chapter 4 and an unfortunate error occurs early on, where it is stated that poles must be positive for transients to decrease with time, although this statement is corrected in the text which follows. The Nyquist criterion and phase-gain method of stability analysis are described, and also the Hurwitz criterion, although not the somewhat simpler one of Routh. Damping and compensation are also discussed. The brief discussion of non-linear systems in the following chapter includes a derivation of the parabolic response of an on-off system, but no mention of phase-plane or other analytical methods.

In the final chapter, typical examples of simple controllers taken from the mechanical, electrical, hydraulic and pneumatic fields are described. Thus the author reinforces the point made at the outset and maintained throughout the book, that linear theory is applicable in all these fields and that the student of control must be aware of this and appreciate the merits of each. Despite its conciseness, the presentation, apart from the errors mentioned, is exceedingly clear, and this small volume is ideal for students and should be very valuable in teaching the subject.

In a very different category of price, size and purpose is the volume entitled *Automatic Control Handbook*. Using a minimum of mathematics but with many photographs and diagrams, this book describes the principles of operation and the application of many of the components and devices of automatic control. Among the twenty-one chapters contributed by different experts are those devoted to motors, relays, magslips and selsyns, magnetic and rotating amplifiers, voltage and temperature control, materials, transducers, photoelectrics and nucleonics, analogue computers, mechanical handling, lubrication, hydraulic and pneumatic control, machine-tool control, gyroscopes and television. Digital systems receive little attention, and this is perhaps the most significant omission in an otherwise comprehensive list. The nature of this work is such that the words "feed-back", "transfer function" and "non-linearity" seldom appear and, as is to be expected in a composite edition such as this, there is no thread of theory relating the various chapters. This is particularly noticeable on reaching the chapter devoted to analogue computers which outlines methods of solving problems which can only be formulated with the aid of basic feed-back theory. Thus, while not attempting to study the closed-loop problem, this volume will none the less be valuable to the designer as an aid to the selection of methods or components, which for problems in open-loop control is often all that is required. A number of advertisements are included, as well as a comprehensive index.

Anatomy of Automation is described as a "broad survey of production and automation trends to aid business executives and production men". This book is mainly concerned with definitions and classification, and in the first chapter the authors define a "scale of automation" containing ten groups and given the symbol A, which they compare with the symbol F used to represent the Fahrenheit scale of temperature. A chapter recognizing the office, military, domestic and industrial fields of automation is followed by an examination of various production operations with the view of classification.

The remaining chapters are devoted to describing the levels of automation which have been found advantageous in various situations, and thus to aiding the industrialist in making the necessary decisions in this direction. The book is completely non-mathematical, to a large extent non-technical, and is well supplied with illustrations. An index and bibliography are provided.

E. M. Deeley

NUTRITION OF PIGS AND POULTRY

Nutrition of Pigs and Poultry

Proceedings of the University of Nottingham Eighth Easter School in Agricultural Science, 1961. Edited by Dr. J. T. Morgan and Dr. D. Lewis. Pp. ix + 366. (London: Butterworth and Co. (Publishers), Ltd., 1962.) 70*s*.

THOSE who have attended Easter Schools of the University of Nottingham are in no doubt of the quality of the papers presented and of the liveliness of the subsequent discussions. Not all authorities on their special subjects are equally expert in the art of oral presentation, and few listeners are capable of assimilating all the views and facts presented at the time. The subsequent publication of the *Proceedings* with discreet editing of both papers and discussion is therefore always to be welcomed; it provides a stimulating 'refresher" for those who attended, and to the wider range of readers who could not be present, a comprehensive review of up-to-date information in the numerous fields embodied in the subject of the School. Indeed, it goes further, for in the presentation of the present position of knowledge of a particular topic, it helps to emphasize the gaps in knowledge and the directions in which new research is urgently required. The organizers of these Schools are sufficiently far-sighted, to the extent that their resources will permit, to invite speakers from the United States and from various European countries to make specifis contributions. Language difficulties are largely eliminated by skilful editing, and the net result is that these *Proceedings* represent an authoritative work of great value. Workers in the field of nutrition of pigs and poultry are very conscious of the value of research from other countries, and the present volume is enhanced by the contributions from outside the United Kingdom.
